1 INTRODUCTION

Information on the tertiary structure of membrane proteins has been difficult to obtain due to the heterogeneous environment of these proteins. Although crystallography has provided detailed information for a small number of membrane proteins, it is often difficult to obtain crystalline material for high-resolution diffraction studies. In the case of smaller peptides, such as gramicidin¹ and the M13 coat protein,² solid state NMR methods have proven capable of obtaining detailed structural information of the peptide within phospholipid bilayers. In addition, there have been numerous high-resolution solution NMR studies on small peptides and proteins bound to detergent micelles.^{2,3}

The application of either solution phase NMR or solid state NMR to larger membrane proteins is fraught with difficulties. In the case of solid state NMR techniques, it is often difficult to obtain protein that is labeled at a small number of unique sites. The routine application of multidimensional NMR experiments, which are commonly used for structure determination, cannot be applied to large protein-lipid complexes because of the short spin-spin relaxation time. In view of these limitations, we and others⁴⁻⁶ have explored the use of ¹⁹F NMR as a method of obtaining information on the structure and dynamics of membrane associated proteins. Fluorine-19 is a particularly useful NMR nucleus to observe because it has high sensitivity, 100% natural abundance, a large dispersion of chemical shift, and is not normally found in biopolymers. The relaxation properties of the ¹⁹F spin can be used to obtain information on the internal motion of amino acid residues within the protein molecule.

In order to apply ¹⁹F NMR techniques to proteins, it is necessary to incorporate a fluorine atom into the membrane protein at a small number of sites. The incorporated ¹⁹F spins would then serve as probes for the local environment and dynamics of regions of the protein. Fluorinated analogs of aromatic amino acids have been used to incorporate fluorine biosynthetically into several proteins without noticeable effects on protein function. Examples include alkaline phosphatase

(F-Tyr),⁷ lac repressor (F-Tyr),⁸ λ-cro protein (F-Phe, F-Tyr),⁹ D-lactate dehydrogenase (F-Trp),⁵ D-galactose receptor protein (F-Trp),⁶ and retinol binding protein (F-Trp).¹⁰

As a model system in which to apply ¹⁹F NMR to the study of protein-lipid interactions, we have selected the membrane-associated enzyme D-lactate dehydrogenase (D-LDH) of *Escherichia coli*. This flavin containing enzyme has a molecular weight of 65 000 and catalyzes the oxidation of D-lactate to pyruvate in an electron transfer reaction that is coupled to the active transport of various amino acids and sugars into membrane vesicles.^{11,12} The enzyme is located on the cytoplasmic face of the cell membrane.¹³ The purified enzyme requires a lipid-like environment to prevent aggregation, and various lipids and detergents enhance its stability and activity.^{5,12,14} Therefore, D-LDH appears to be an excellent model system in which to study protein-lipid interactions. To investigate these interactions, we have used ¹⁹F NMR methods to address the following important questions: Is the structure of the protein altered by the presence of lipid? What is the topology of the protein-lipid complex? How are the motional properties of residues in D-LDH related to their microenvironment?

Before initiating NMR studies on D-LDH, it was necessary to obtain large amounts of fluorine labeled material. This was accomplished by overproduction of the enzyme in *E. coli* using recombinant DNA techniques.¹⁵ D-LDH labeled with F-Phe or F-Tyr proved to be unsuitable for detailed ¹⁹F NMR studies because the spectra of the labeled material contain large numbers of unresolved peaks. In contrast, ¹⁹F NMR spectra obtained from 4F-, 5F-, and 6F-Trp labeled material were largely resolved. Since 5F-Trp labeled D-LDH produced the most resolved spectrum, it was used for the studies directed at investigating lipid induced conformational changes and mapping the topology of the enzyme. Nuclear spin relaxation measurements were performed with both 4F-Trp and 5F-Trp labeled material.

2 PROTEIN-LIPID INTERACTIONS

The effect of lipid on the conformation of D-LDH was assessed by acquiring the ¹⁹F NMR spectra of 5F-Trp labeled D-LDH in the presence of different lipids. To determine the location of lipid-induced changes in the structure of D-LDH it is necessary to assign the resonance lines in the ¹⁹F NMR spectrum of 5F-Trp labeled D-LDH. To accomplish this, a series of mutant enzymes were made in which each of the native Trp residues was replaced with Phe or Tyr. The resultant ¹⁹F NMR spectrum of each mutant lacks a single resonance line, but is otherwise identical to that of the wild-type enzyme (Figure 1), suggesting that the mutation has not perturbed the environment of the remaining Trp residues. This method was originally used to assign ¹⁹F resonance lines in F-Tyr labeled lac repressor,⁸ and has been applied to other fluorine labeled proteins as well.⁶

Fluorine-19 NMR spectra of 5F-Trp labeled D-LDH in different lipid environments is shown in Figure 2. On the basis of chemical shift changes it appears that the conformation of D-LDH is similar in detergent micelles of Brij (heptaethylene glycol dodecyl ether), micelles of lysolecithin, and vesicles of DPPG (dipalmitoylphosphatidylglycerol). In

Figure 1 Assignment of ^{19}F NMR resonances for D-LDH labeled with 5F-Trp. Fluorine-19 NMR spectra were obtained at 282.4 MHz and at 42°C in 10 mM phosphate buffer containing 100 mM lysolecithin and 1–2 mM D-LDH. (Reproduced by permission of Academic Press from Rule et al.⁵)

contrast, chemical shift changes are noted in the presence of other detergents.

The ^{19}F resonances observed in the presence of DPPG are too broad to give spectra of useful resolution. However, adequate resolution of the resonances is obtained in the presence of lysolecithin because of the smaller size of this protein–lipid complex. Since the conformation of the protein appears to be similar in both of these lipids, studies performed in lysolecithin should provide information on D-LDH in a native environment.

3 TOPOLOGY OF D-LDH

The goal of these studies was to define the topology of D-LDH by determining the solvent exposure, lipid exposure, and sensitivity to substrate binding of each fluorinated residue in D-LDH. The ^{19}F NMR spectra of D-LDH can only provide information on regions of the protein which are in the vicinity of the native Trp residues (positions 59, 384, 407, 469, and 567). To provide information from other locations within the protein, additional Trp residues have been introduced into the protein by replacing hydrophobic residues with Trp. A total of 32 Trp substitution mutants have been constructed.^{16–18}

In some cases the substitution of a residue by Trp results in the production of either an inactive protein or a temperature sensitive folding mutant.¹⁷ Presumably, replacement of some residues by Trp can disrupt the packing within the interior of the protein.¹⁹

Although some of the mutants were found to be inactive, a large number are not perturbed by the substitution of a residue by Trp. Spectra for nine enzymatically active Trp substitution mutants are shown in Figure 3. In all cases, it is possible to observe an additional spectral line that arises from the new Trp residue. In some cases, the resonance line from the added Trp residue is well resolved from those of the native Trp residues.

The native Trp residues and the active Trp substitution mutants can provide information for 27 positions which are uniformly distributed over the length of the protein. The solvent exposure of each residue has been quantified by measuring the change in chemical shift of the resonance line when the solvent is changed from H_2O to D_2O .^{5,20} The proximity of each labeled site to the lipid phase can be assessed by measuring the paramagnetic broadening of the resonance lines when the nitroxide labeled fatty acids are included in the lipid phase. Figure 4 shows the effects of paramagnetic broadening on the spectrum from the Trp substitution mutant

Figure 2 Fluorine-19 NMR spectra (282 MHz) of 5F-Trp labeled D-LDH in the presence of different lipids and detergents. In the Triton-X100 sample, it was necessary to use a low concentration of protein to prevent aggregation. (Reproduced by permission of Academic Press from Rule et al.⁵)

F361. It is clear from this spectrum that this residue is close to the lipid bilayer.

The effect of substrate binding on the properties of the NMR resonances was also monitored to determine which areas of the protein may participate in catalysis. A particular example is that of Trp 469, whose resonance line undergoes a shift and broadening in the presence of substrate.⁵ Figure 5 summarizes the results obtained for solvent isotopic shift, paramagnetic broadening, and substrate effects for all 27 locations throughout the molecule. This figure clearly demonstrates that the lipid binding domain of D-LDH has a unique characteristic that is distinct from other membrane proteins of known structure. The lipid binding domain of D-LDH appears to be composed of small discontinuous regions of the protein, containing residues 228, 243, 280, 309, 361, and 369.¹⁸ This region of the protein is likely to be the site which transfers reducing equivalents to the electron transport chain.

4 DYNAMICS OF Trp RESIDUES IN -LDH

The relaxation properties of the ¹⁹F nuclear spin can provide important information on protein dynamics. Both the dipolar

interaction with adjacent protons and the CSA contribute to the relaxation of the ¹⁹F spin. The effect of dipolar coupling on the spin-lattice (T_1) and spin-spin (T_2) relaxation times have been derived by Solomon.²¹ Abragam²² gives the following expressions for relaxation due to the CSA:

$$\frac{1}{T_1} = \frac{6}{40} \omega_0^2 (\sigma_{zz} - \sigma_{iso})^2 \left[1 + \frac{\eta^2}{3} \right] J(\omega_0) \quad (1)$$

$$\frac{1}{T_2} = \frac{1}{40} \omega_0^2 (\sigma_{zz} - \sigma_{iso})^2 \left[1 + \frac{\eta^2}{3} \right] [2J(\omega_0) + 4J(0)] \quad (2)$$

where ω_0 is the Larmor frequency of the fluorine nucleus, $(\sigma_{zz} - \sigma_{iso})$ is the z component of the traceless part of the chemical shift tensor, η is the asymmetry parameter, and $J(\omega)$ is the spectral density function that describes the frequency spectrum of the random molecular motion. Since the contribution of the chemical shift tensor to relaxation is dependent on the square of the field, measurements of relaxation times at different field strengths can be used to determine the contribution of CSA to relaxation of the nuclear spin.

The analytical form of the spectral density function that is used in these calculations is dependent on which model is used to describe the motion of the fluorinated aromatic side

Figure 3 Fluorine-19 NMR spectra (282 MHz) of 5F-Trp labeled wild-type D-LDH and nine active Trp substitution mutants. The concentration of protein is approximately 1 mM in 100 mM lysolecithin, 10 mM phosphate, and 0.2 mM EDTA at pH 7.2 and 42 °C. The arrows indicate the additional resonance from the new Trp residue. (Reproduced by permission of Academic Press from Peersen et al.¹⁶)

chain. Earlier work by Hull and Sykes²³ modeled the internal motion of the F-Tyr residues in alkaline phosphatase as axially symmetric diffusion about the $C_{\beta\gamma}$ bond. A similar approach was used by Dettman et al.⁴ in the analysis of F-Phe and F-Tyr side-chain mobility in the M13 coat protein. In the case of D-LDH, the relaxation data were also interpreted within the context of specific molecular model of motion. This approach was taken because the relaxation properties of each positional isomer (i.e. 4F-Trp versus 5F-Trp) are uniquely sensitive to a particular type of motion.

We have considered two simple models of internal rotation: rotation about the $C_{\alpha\beta}$ bond and rotation about the $C_{\beta\gamma}$ bond. The spectral density functions for rotation about these bonds were obtained using the model dependent approach described by Wittebort and Szabo.²⁴ The effect of the rate

of independent internal rotation about these two bonds on the T_1 , T_2 , and the heteronuclear (proton-fluorine) NOE is shown in Figure 6. These calculations assume isotropic rotation about the indicated bond; however, similar results are also obtained for large amplitude oscillations about the same axis. Although relaxation due to CSA and intraresidue heteronuclear dipolar coupling was considered in these calculations, it is not possible to calculate interresidue heteronuclear interactions; thus, these calculations should only be regarded as approximate. An important feature of the calculated relaxation parameters is that there are differences in the relaxation properties of 4F-Trp versus those observed with 5F-Trp. A comparison of the relaxation properties of each isomer provides a qualitative description of the type and rate of internal motion of Trp residues in D-LDH.

Figure 4 Fluorine-19 NMR spectra (282 MHz) of 5F-Trp labeled mutant D-LDH (Phe361 altered to Trp). Spectra were obtained in 100 mM lysolecithin, 10 mM phosphate, and 0.2 mM EDTA at pH 7.2 and 42 °C (bottom spectrum), or with the addition of 28 mM 8-doxylpalmitic acid (top spectrum). The arrow indicates the resonance that is severely broadened by the spin label. (Reproduced by permission of Academic Press from Peersen et al.¹⁶)

Experimental data collected on 4F- and 5F-Trp D-LDH included the effect of magnetic field strength on T_1 and T_2 , and the heteronuclear NOE. The heteronuclear NOE and contribution of the CSA to the linewidth are given in Table 1. All residues show heteronuclear NOE values which are greater than -1 , suggesting internal motion of these Trp residues. Figure 6 shows that the rate of internal rotation ($\tau_{1,2}$) is not uniquely determined by measurement of the NOE. However, it has been shown²⁶ that the T_1 increases as the magnetic field strength is increased, suggesting that the rate of internal rotation of all of the Trp residues in D-LDH possesses relatively slow rates of internal rotation (i.e. $\tau_{1,2} < 10^{-9}$). The five Trp residues in D-LDH can be divided into three groups on the basis of a comparison of the measured NOE and linewidth due to the CSA. Trp residues at positions 59 and 469 show heteronuclear NOEs and CSA linewidths that are larger for 4F-Trp versus 5F-Trp. Calculated values of the NOE and linewidth [Figure 6(a)] suggest that these Trp residues are most

Figure 5 A summary of results from ^{19}F NMR observations of 5F-Trp labeled wild-type D-LDH and D-LDHs containing Trp substitution mutations. In general, open ovals indicate observed, but small, effects, and solid ovals indicate major effects. Substrate sensitivity: (○) 20–50% broadening, or <0.2 ppm shift; (●) $>50\%$ broadening, or >0.2 ppm shift. Sensitivity to spin labeled lysolecithin: (○) slight broadening; (●) loss of resonance from spectrum. Solvent exposure: (○) exposure index <0.25 ; (●) index >0.25 (index of 1.0 reflects shift of free 5F-Trp in solution). A vertical line indicates that no effect was seen. (Reproduced by permission of Cambridge University Press from Sun et al.¹⁸)

Table 1 Relaxation Data for 4F- and 5F-Trp-labeled D-LDH

	Trp59	Trp384	Trp407	Trp469	Trp567
$^1\text{H}-^{19}\text{F}$ NOE					
4F-Trp	−0.70	−0.90	−0.90	−0.70	−0.90
5F-Trp	−0.90	−0.80	−0.80	−1.00	−0.75
CSA linewidth ^a					
4F-Trp	105	100	155	100	170
5F-Trp	52	68	34	53	040

^aContribution of chemical shift anisotropy to the linewidth at 282 MHz.

Figure 6 Effects of internal rotation on T_1 , T_2 , and heteronuclear NOE as a function of τ_1 and τ_2 : (a) rotation about the $C_{\alpha\beta}$ bond with correlation time τ_1 ; (b) rotation about the $C_{\beta\gamma}$ bond with correlation time τ_2 . The calculated T_1 (■, □), T_2 (▲, △), and the NOE (▼, ▽) are shown as functions of the correlation time for the internal rotation for 5F-Trp (solid symbols) and for 4F-Trp (open symbols). The correlation time for the overall rotation of the enzyme, τ , is 6×10^{-8} second and the ^{19}F frequency is 282.4 MHz. (Reproduced by permission of Elsevier Science Publishers from Ho et al.²⁵)

likely undergoing motion about the $C_{\alpha\beta}$ bond with a correlation time that is slower than 10^{-8} second. This finding supports the conjecture that these two residues are buried in the protein core (see Figure 5). Trp residues at positions 407 and 567 show the opposite effect; the measured values for 5F-Trp exceed those obtained for 4F-Trp. Figure 6(b) suggests that this second group of Trp residues is predominately undergoing rotation about the $C_{\beta\gamma}$ bond with a correlation time of 10^{-8} – 10^{-9} second. Since these two residues are exposed to the solvent (see Figure 5), it is reasonable to expect a considerable amount of internal motion. In fact, the motion of Trp567 seems to be enhanced in the presence of DPPG since the resonance line from Trp567 is relatively sharp in the presence of DPPG (see Figure 1). Trp384 is a singular member of a class which shows a larger NOE for 4F-Trp but a narrower CSA linewidth for 5F-Trp. Clearly, the motion of Trp384 is not well described by the simple models of internal motions used here.

In summary we have demonstrated that ^{19}F NMR methods can provide considerable information from rather large membrane proteins in complex with detergent-like molecules. The utility of this method is greatly enhanced by the ability to use recombinant DNA methods to introduce additional NMR probes into the structure. These additional probes can be used to obtain information on the local environment and dynamics of the protein.

1 STUDYING ENZYME MECHANISM BY ^{13}C NMR

Almost all enzymatic processes utilize multistep reactions during catalysis, and the characterization of each of these stages is essential if one is to understand enzyme mechanism at the molecular level. Earlier investigators used spectrophotometric methods for characterizing enzyme-catalyzed reactions, whereas inhibitors that form stable ‘transition state analogs’ were examined using other techniques that require long periods of data accumulation, for example, X-ray analysis. However, the use of NMR in enzymology is beginning to provide a novel and penetrating probe for elucidating enzyme mechanism by directly characterizing intermediates formed in catalysis. The studies of transition state analogs allow access to the unique properties of enzymes that enable them to stabilize labile intermediates and therefore achieve their remarkable catalytic efficiency. We discuss first the structure of an enzyme–inhibitor adduct of the serine protease trypsin and compare the results of direct observation by ^{13}C NMR with the structural information inferred by more classical techniques. We then review the powerful combination of NMR and cryoenzymology. The marriage of the two techniques whereby enzyme-catalyzed reactions are studied at subzero temperatures in aqueous organic solvents (cryosolvents), allows such reactions to be slowed down and can prolong the lifetime of enzyme–substrate intermediates.¹ Finally we discuss the use of ^{13}C -enriched cofactors to study molecular events at the active site.

Figure 1 shows the generally accepted mechanism for the hydrolysis of an amide function by a serine protease. To confirm this mechanistic pathway, the visualization and rigorous characterization of productive tetrahedral intermediates and acyl enzymes by ^{13}C NMR is the ultimate goal, and we now discuss the progress made so far, particularly with regard to the serine and thiol proteases.

In the domain of synthetic inhibitors, chloromethyl ketone derivatives of specific substrates are potent irreversible covalent inhibitors of the serine proteases, alkylating the active-center histidine at N-2. X-ray crystallographic studies led to the suggestion that, in addition to the above alkylation, there was

Figure 1 Serine protease mechanism

also nucleophilic attack by the active-center serine hydroxyl to form a hemiketal, which is stereochemically analogous to the tetrahedral intermediate purported to occur during catalysis.²

To test this suggestion, trypsin was inhibited with the highly specific reagent *N*- α -benzyloxycarbonyllysyl chloromethyl ketone (RCOCH₂Cl), labeled in the ketone carbon with 90% ^{13}C , for it was predicted that a tetrahedral adduct, if formed,

Figure 2 Formation of tetrahedral complex of trypsin with (Z)-Lys chloromethyl ketone (CMK)

would be directly observable by this technique. In aqueous solution (Figure 2) RCOCH_2Cl exists as a mixture of the ketone ($\delta = 204.7$ ppm) and its hydrate ($\delta = 95.4$ ppm). At pH 3.2 no alkylation or inhibition of the enzyme is observed and the spectrum of $[\text{}^{13}\text{C}=\text{O}] \text{RCOCH}_2\text{Cl}$ is unperturbed [Figure 2(b) and 2(c)], showing that at low pH there is no detectable binding or tetrahedral adduct formation prior to alkylation. At pH 6.9 there is rapid, irreversible inhibition, and resonances due to both $[\text{}^{13}\text{C}=\text{O}] \text{RCOCH}_2\text{Cl}$ and its hydrate are replaced by a single resonance at 98.0 ppm [Figure 2(d)], an indication that the ^{13}C enriched carbonyl of the inhibitor is tetrahedrally coordinated in the inhibitor–enzyme adduct. Denaturation of the trypsin led to reappearance of a carbonyl resonance (205.5 ppm) and a decrease in the intensity of the resonance at 98.0 ppm. This demonstrates that the tetrahedral adduct formed by the attack of the serine hydroxyl on the inhibitor carbonyl and characterized by the resonance at 90.0 ppm requires an intact trypsin structure.³

Figure 3 ^{18}O shifted ^{13}C NMR spectra of (Z)-Lys CMK complex with trypsin

Figure 4 Bond distances in (Z)-Lys CMK with trypsin from X-ray data at 0.2 nm resolution

In the above experiments with $[\text{}^{13}\text{C}=\text{O}] \text{RCOCH}_2\text{Cl}$ and trypsin it is difficult to discount the possibility that the resonance at 98.0 ppm could result from hydration of the carbonyl of the covalently bound inhibitor. However, the use of ^{18}O isotopic shifts on the ^{13}C spectrum of the tetrahedral adduct shows that the adduct is indeed formed by nucleophilic attack of the Ser^{195} hydroxyl group (Figure 3), a result completely confirmed by X-ray diffraction studies as portrayed in Figure 4.⁴

2 THE QUEST FOR TRUE INTERMEDIATE STRUCTURE: CRYOENZYMOLOGY

The detection and characterization of a productive, short-lived acyl intermediate by ^{13}C NMR during catalysis with natural substrates at ambient temperature is not possible at present, because there is an inherent lack of sensitivity in ^{13}C NMR spectroscopy. Therefore, the lifetimes of these intermediates must be extended into the domain of the NMR experiment. One approach is to utilize cryoenzymological techniques to extend the lifetimes of such intermediates.

Since the ^{13}C NMR resonance of the carbonyl of a thioester is shifted 20–30 ppm from that of the oxygen analog, ^{13}C NMR spectroscopy should allow the direct monitoring of the formation and decay of a thioacyl intermediate during thiol protease catalysis. Using $[\text{}^{13}\text{C}=\text{O}] N$ -benzoylimidazole ($\delta = 168.7$ ppm) as substrate, it is possible to observe directly a thioacyl intermediate at $\delta = 195.9$ ppm in the presence of the thiol protease, papain, under the cryoenzymological conditions of -20°C in 25% aqueous dimethyl sulfoxide.⁵ Moreover, the thioacyl species is clearly a productive intermediate since the decrease in its signal intensity is accompanied by an increase in the product resonances and by release of free enzyme determined by titration of its thiol group. The linewidth of the resonance at 195.9 ppm was $25 \pm 2 \text{ Hz}$.^{5,6} Similarly, the trypsin catalyzed hydrolysis (Figure 5) of the highly specific substrate N - α -benzyloxycarbonyl-L-lysine p -nitrophenyl ester [(Z)-Lys- p -NP] has been studied in detail under cryoenzymological conditions by both spectrophotometry and ^{13}C NMR spectroscopy.⁶ The kinetic data from both techniques confirm

Figure 5 (a) Trypsin-catalyzed hydrolysis of (Z)-Lys-*p*-NP. (b) Time course of hydrolysis of (Z)-Lys-*p*-NP (¹³C=O) by trypsin

that the kinetics and mechanism under cryoenzymological conditions are essentially the same as those determined at ambient temperatures by rapid reaction techniques. The hydrolysis of [¹³C](Z)-Lys-*p*-NP [(S) in Figure 5, $\delta = 173.6$ ppm] by trypsin was monitored by the decrease in intensity of this signal and the increase in the signal arising from the product (P₂ in Figure 5, $\delta = 177.7$ ppm) at -21°C in 41% aqueous dimethyl sulfoxide. The continued formation of product (P₂) after all the substrate has been consumed [Figure 5(b)] provides indirect evidence for an enzyme-bound intermediate whose linewidth is much greater than that of the free substrate or product and is therefore not directly observable in the individual ¹³C NMR spectra shown in Figure 5. Improvement of the signal-to-noise ratio by summation of sets of the individual spectra in

Figure 6 Difference NMR spectra at (a) -1.5°C and (b) -21°C, showing signals for acyltrypsin

Figure 5 made it possible to use difference techniques and allowed direct observation at -21°C of a resonance ($\delta = 176.5$ ppm) that was assignable to the acyl enzyme on the basis of its chemical shift and the kinetics of its breakdown-formation.

Experiments at -1.5°C [Figure 6(a)] showed that the acyl intermediate was much more readily detected at this higher temperature, the resonance being clearly resolved in the individual spectra as a result of the smaller linewidth of the resonance at -1.5°C compared with that at -21°C, 22 ± 3 Hz and 100 ± 10 Hz respectively. This illustrates one of the main difficulties of a combined NMR-cryoenzymological approach in which the linewidth of enzyme-bound species increases dramatically as the cryosolvent viscosity increases on lowering the temperature. In recent studies with chymotrypsin modified by replacement of His-57 by *N*-methyl-His-57, stabilization of the acyl intermediate was achieved⁷ at room temperature (Figure 7).

3 SOLID STATE NMR AS A PROBE FOR ENZYME-SUBSTRATE STRUCTURE

The basis for the NMR studies with proteases has relied heavily on the crystal structure determination of the enzyme and/or enzyme complex at the active site. Since the phase change from solid to solution may well involve considerable conformational alteration, the correlation of the two physical

Figure 7 Hydrolysis of *N*-acetyl-L-Phe-OEt by *N*-3-methylhistidinyl- α -chymotrypsin at ambient temperature

methods (X-ray, NMR) in the same phase would be a desirable objective in furthering our understanding of enzyme mechanism. Our next theme concerns the application of solid state cross polarized magic angle spinning (CP MAS) NMR spectroscopy to the direct observation of the hydrolysis of a slow (pseudo) substrate catalyzed by an enzyme. MAS NMR has already been shown to be a powerful technique for the study of solids generally⁸ and has been used extensively in inorganic systems.⁹

The crystal structures of several complexes of the metallo enzyme, carboxypeptidase A α (CPA) (EC 3.4.17.1), have been examined in considerable detail.¹⁰ The structure of the complex with glycytyrosine (Gly-Tyr) has been refined to 0.2 nm resolution and reveals, inter alia, interactions between the amide carbonyl oxygen and the catalytically essential zinc, and between the amide nitrogen and the hydroxyl of Tyr-248 (Figure 8). The proposed mechanisms for hydrolysis of peptide and ester bonds by CPA have relied heavily on these crystal structures, but a clear distinction between the possible roles of glutamate-270 (Glu-270) in nucleophilic attack either by general base catalysis [Figure 8(a)] or by covalent anhydride formation [Figure 8(b)] remains a major unresolved problem. Indeed, it is not yet certain whether esters and amides are hydrolyzed by CPA via identical mechanisms.

Gly-Tyr was synthesized as both the [¹³C]amido (90 atom % enrichment) and amido[¹³C,¹⁵N] (90 % atom enrichment, respectively) isotopomers by known methods. CPA soaked with Gly-Tyr crystals was examined using solid state NMR. The ¹³C CP MAS NMR spectrum of the ¹³C-enriched Gly-Tyr substrate [Figure 9(a)] displays residual ¹⁴N,¹³C quadrupolar coupling ($\delta = 176$ ppm). However, the ¹³C CP MAS difference spectrum of CPA and the CPA/Gly-Tyr complex [Figure 9(b)] displays a single resonance ($\delta = 178$ ppm, linewidth at halfheight 60 Hz), revealing that, under the experimental

Figure 8 Two possible mechanisms for the hydrolysis of Gly-Tyr by CPAse

Figure 9 ¹³C CP MAS spectrum of Gly-Tyr, showing the disappearance of quadrupolar coupling (¹⁴N,¹³C) after reaction with CPAse

conditions, the peptide bond of this slow reacting substrate has been cleaved to the extent of >90%. In order to confirm this result, doubly labeled amido [¹³C,¹⁵N]Gly-Tyr (not shown) was bound to CPA under identical conditions and the complex examined by ¹⁵N NMR. The resonance of the substrate ($\delta = 120$ ppm) is sufficiently broad (linewidth at halfheight 325 Hz) to conceal the ¹⁵N,¹³C one-bond scalar coupling

($J = 16$ Hz). In the enzyme complex (not shown), the observed ^{15}N resonances correspond to the amide region of CPA ($\delta = 122$ ppm, linewidth at halfheight = 400 Hz) and an amine ($\delta = 42$ ppm, linewidth at halfheight = 250 Hz), respectively.

We infer from these experiments that we are observing either the first stable intermediate of the catalytic pathway, i.e. the anhydride of the cleaved glycine residue bound covalently to Glu-270 (Figure 8), or the bound glycine accompanied in either case by the second product, tyrosine (Figure 8) also bound to CPA, since in a separate experiment it could be shown that no unbound tyrosine or glycine was present in the complex. A distinction between the two glycine species (anhydride or acid) cannot be made at this stage since the ^{13}C chemical shifts of the carbonyl(s) in both the anhydride and the acid are within the observed chemical shift range. However, these preliminary experiments¹¹ clearly indicate the feasibility of simultaneous X-ray and CP MAS NMR studies, especially with slow substrates. In summary, a method of some generality for reaching the long-sought correlation between X-ray diffraction data, the resultant geometry of a substrate undergoing slow catalysis, and the corresponding NMR chemical shifts for selected atoms in the enriched substrate, obtained under identical conditions, is now available through the use of the CP MAS technique.

Recently, the application by Evans¹² of solid state NMR to freeze-quenched systems has revealed by ^{13}C enrichment of the substrate, the time course of the reaction catalyzed by 5-enolpyruvylshikimate synthase. This elegant study¹² paves the way for further correlation of structure between NMR and time resolved Laue X-ray diffraction.

From the discussion presented above, it is clear that the stage is now set for intensive research into the mechanism of enzyme action with cryoenzymology. Although most of the enzymes discussed above lie in the molecular weight range of 20–35 kDa, an upper figure of 100 kDa probably represents the maximum convenient size for ^{13}C NMR studies on currently available superconducting instruments with substrates and inhibitors. However, even with high molecular weight enzymes, labeling the coenzyme or a cofactor can give excellent results, as discussed in the two final examples.

4 COFACTOR ENRICHMENT

1. The use of ^{13}C -labeled coenzyme pyridoxal phosphate ($^{13}\text{CHO-PLP}$) in the reactions catalyzed by cytosolic aspartate amino transferase (EC 2.6.1.1) (cAAT), a dimeric protein ($M_r = 90$ kDa), allows clear observation of both internal and external aldimine forms with inhibitors such as methyl aspartate, as shown in Figure 10.¹³
2. Tetrapyrrole biosynthesis, which is responsible for heme, chlorophyll and vitamin B₁₂ formation, begins with the self-condensation of aminolevulinic acid (ALA) to porphobilinogen (PBG). Next PBG deaminase, encoded by *hemC*, catalyzes the tetramerization of PBG (1) to preuro'gen (hydroxymethylbilane, HMB; (2) which is cyclized with rearrangement to the unsymmetrical macrocycle uro'gen III (3) by uro'gen III synthase (Figure 11 and 12). In the absence of the latter enzyme, HMB (2) dehydrates spontaneously to uro'gen I (4), which, although strictly not a

Figure 10 ^{13}C NMR spectrum of cytosolic AAT (cAAT) with (top) PLP (bottom) [4'- ^{13}C]PLP, showing the bound cofactor signal at $\delta = 165.3$ ppm

natural product, turns out to be a substrate for some of the methyltransferases of the vitamin B₁₂ pathway.

Deaminase is an unusually helpful enzyme since a covalent bond is formed between each incoming substrate molecule and enzyme, thus allowing isolation of covalent complexes containing up to 3 PBG units (ES₁–ES₃). With cloned deaminase in hand it was found by ^{13}C NMR that a novel cofactor is covalently attached to one of the four cysteine residues of the enzyme (Cys-242) in the form of a substrate-derived dipyrromethane whose free α position becomes the site of attachment of the succeeding four moles of substrate during the catalytic cycle¹⁴ (Figure 11 and 12).

Thus a mutant strain of *Escherichia coli* (*hemA*⁻ requiring ALA for growth) in the presence of [5- ^{13}C]Ala afforded highly enriched enzyme for NMR studies. At pH 8, the enriched carbon atoms of the dipyrromethane cofactor (py-CH₂-py) were clearly recognized at 24.0 ppm (py-CH₂-py), 26.7 ppm (py-CH₂-X), 118.3 ppm (α -free pyrrole) and 129.7 ppm (α -substituted pyrrole) [Figure 11(a)]. The signals are sharpened at pH 12 [Figure 11(b)] and the CH₂-X resonance is shifted to $\delta = 29.7$ ppm in the unfolded enzyme. Comparison with synthetic models reveals that a shift of 26.7 ppm is in the range expected for an α -thiomethylpyrrole

Figure 11 High field NMR spectra of *E. coli* PBG deaminase (~ 1 mM) specifically ^{13}C -enriched in the dipyrromethane cofactor via $[5\text{-}^{13}\text{C}]\text{Ala}$. (a) 125 MHz ^{13}C NMR difference spectrum between separate deaminase samples (pH 8) grown in the presence or absence of $[5\text{-}^{13}\text{C}]\text{Ala}$ demonstrating the four Ala-derived ^{13}C -enriched carbon atoms. (b) Difference spectrum of samples as in (a), recorded at pH 12. Upon alkaline denaturation, the resonance assigned to thiomethyl carbon has been deshielded to $\delta = 29.7$ ppm, which is in closer agreement to a model cysteine thiomethylpyrrole conjugate. (c) ^{13}C INADEQUATE spectrum (pH 12) of $[5\text{-}^{13}\text{C}]\text{Ala}$ -derived deaminase demonstrating the coupling of adjacent carbon atoms, confirming the head-to-tail dipyrromethane structure. (d) Isotope-edited 300 MHz ^1H NMR spectrum (pH 12) of biosynthetically enriched deaminase (2 mM) showing the three pairs of signals originating from only those protons directly bound to the ^{13}C atoms derived from $[5\text{-}^{13}\text{C}]\text{Ala}$. The observed antiphase splittings are due to the one bond ^{13}C , ^1H coupling. (e) Normal proton spectrum of same sample illustrating the degree of selection afforded by the pulse sequence for spectrum (d). Insert: structure of the dipyrromethane cofactor (5) and summary of ^1H and ^{13}C chemical shifts and coupling constants obtained at pH 12

(py-CH₂-SR). Confirmation of the dipyrromethane (rather than oligo pyrromethane) came from the ^{13}C INADEQUATE spectrum taken at pH 12 which reveals the expected coupling only between py-CH₂-py ($\delta = 24.7$ ppm) and the adjacent substituted pyrrole carbon ($\delta = 128.5$ ppm) [Figure 11(c)]. When the enriched deaminase was studied by ^1H detected heteronuclear filtered spectroscopy [Figure 11(d)], only five protons (in a total of nearly 2000) attached to ^{13}C -enriched nuclei were observed in accord with structure (5) (Figure 12). A specimen of deaminase was then covalently inhibited with the suicide inhibitor $[2,11\text{-}^{13}\text{C}_2]\text{-2-bromo-PBG}$ (8) (Figure 12) to give a spectrum consistent only with structure (9). The site of covalent attachment of substrate (and inhibitor) is therefore the free α -pyrrole carbon of the dipyrromethane cofactor in the native enzyme, leading to the structural and mechanistic proposal for deaminase portrayed in Figure 12.¹⁴

Independent, complementary work in 1987–88 from two other laboratories^{15,16} reached identical conclusions regarding the catalytic site. The ^{13}C -labeling defines the number of PBG units (two) attached in a head-to-tail motif to the native enzyme at pH 8 and reveals the identity of the nucleophilic group (Cys-SH) which anchors the dipyrromethane (and hence the growing oligopyrrolic chain) to the enzyme. Site

specific mutagenesis and chemical cleavage were employed to determine that Cys-242 is the point of attachment of the cofactor.

The use of the α -carbon atom of a dipyrromethane as the nucleophilic group responsible for oligomerization of 4 mol of PBG (with loss of NH₃ at each successive encounter with an α -free pyrrole) is not only remarkable for the exquisite specificity and control involved, but is, as far as we know, a process unique in the annals of enzymology in that the substrate is actually used not only once, but twice, in the genesis of the active site cofactor! Even more remarkable is the fact that the apoenzyme is automatically transformed to the active holoenzyme by addition of two PBG units without the intervention of another enzyme. All of these events were ‘viewed’ by ^{13}C NMR spectroscopy.

This brief account has exemplified the application of the stable isotopes ^{13}C , ^{15}N and ^{18}O in probing enzymatic transformations in vitro. Many examples which are outside the scope of this article are concerned with the isotopic analysis of the products of biochemical conversions. These include applications of ^2H NMR,¹⁷ ^3H NMR,^{17–19} ^{31}P NMR,^{20,21} and $^1\text{H}\{^{13}\text{C}\}$ heteronuclear filtered spectroscopy.^{17,22}

1 INTRODUCTION

Magnetization transfer is a rapid reaction technique which can be used to measure enzyme-catalyzed fluxes with rate constants of the order of $1\text{--}10\text{ s}^{-1}$. These measurements can be made not only in vitro but also in some cases in an intact living system, where this might be anything from microbial cells growing in culture to specific regions of the human brain. The techniques for measuring transfer of magnetization, which were discussed in detail and applied by Forsén and Hoffman,¹ were first applied to an enzyme-catalyzed reactions in vitro by Brown and Ogawa who measured exchange in the reaction catalyzed by adenylate kinase,² and by Brown and Cheshnovsky, who measured the rate of the reversible hydration of acetaldehyde catalyzed by carbonic anhydrase.⁵⁴ The first measurements made in vivo were also made by Brown and co-workers, who measured flux between inorganic phosphate (Pi) and adenosine triphosphate (ATP) in cells of the bacterium, *Escherichia coli*.³ Since that time there have been numerous magnetization transfer studies of enzyme-catalyzed exchange both in vitro and in vivo. These have been discussed in a number of reviews.^{4–7} I will concentrate here on applications of the technique in ³¹P NMR measurements in vivo. Applications in whole body MR spectroscopy are also discussed elsewhere in the Encyclopedia.

2 THEORY AND EXPERIMENTAL METHODS

When the exchange rate constant is comparable to the spin–lattice relaxation rate and separate resonances are observed for the exchanging species then it is possible to determine the rate of exchange by measuring the transfer of nuclear polarization from one resonance to another. In ³¹P NMR measurements in vivo, the spin–lattice relaxation rates are of the order of $0.1\text{--}1\text{ s}^{-1}$.

Consider a two-site exchange system in which a nucleus exchanges between two sites, A and B.

The z magnetizations of the A (M_A) and B (M_B) spins are described by the Bloch equations, which have been modified to include this exchange:

$$dM_A/dt = -\rho_A(M_A - M_0^A) - k_{+1}M_A + k_{-1}M_B \quad (2)$$

$$dM_B/dt = -\rho_B(M_B - M_0^B) - k_{-1}M_B + k_{+1}M_A \quad (3)$$

where M_0^A and M_0^B are the equilibrium z magnetizations of the A and B spins and ρ_A and ρ_B are their spin–lattice relaxation rates. The solutions of these equations are:

$$M_{A(t)} = C_1 \exp(\lambda_+ t) + C_2 \exp(\lambda_- t) + M_0^A \quad (4)$$

$$M_{B(t)} = C_3 \exp(\lambda_+ t) + C_4 \exp(\lambda_- t) + M_0^B \quad (5)$$

where $C_3 = C_1(\lambda_+ + \rho_A + k_{+1})/k_{-1}$ and $C_4 = C_2(\lambda_- + \rho_A + k_{+1})/k_{-1}$ and the constants C_1 and C_2 are determined by the values of M_A and M_B at $t = 0$. The quantities λ_+ and λ_- are given by:

$$\begin{aligned} \lambda_{+/-} = 1/2(-(\rho_A + k_{+1} + \rho_B + k_{-1}) \\ + / - \{[(\rho_A + k_{+1}) - (\rho_B + k_{-1})]^2 + 4k_{+1}k_{-1}\}^{1/2}) \end{aligned} \quad (6)$$

Equations for exchange between three or more sites are of the same form as equations (2) and (3). Although there are no analytical solutions for systems containing more than four sites,⁷ it is straightforward to solve the equations numerically.

There are several magnetization transfer experiments which can be used to measure the exchange rates in a simple two-site exchange system.⁸

2.1 Selective Inversion

If a selective 180° pulse is applied to the B spin then in general its resonance will undergo a nonexponential recovery towards its equilibrium value while the intensity of the A resonance undergoes a transient decrease in intensity. The z magnetization of the A spin at time t is given by:

$$M_{A(t)} - M_0^A = \frac{-2M_0^B k_{-1}}{\lambda_+ - \lambda_-} [\exp(\lambda_+ t) - \exp(\lambda_- t)] \quad (7)$$

while the magnetization of the B spin is given by:

$$\begin{aligned} M_{B(t)} - M_0^B = \frac{-2M_0^B}{\lambda_+ - \lambda_-} [(\rho_A + k_{+1} + \lambda_+) \exp(\lambda_+ t) \\ - (\rho_A + k_{+1} + \lambda_-) \exp(\lambda_- t)] \end{aligned} \quad (8)$$

The exchange rate constants can be obtained either by fitting the data to these solutions or initial rates can be measured to give $(\rho_B + k_{-1})$ for B and k_{+1} for A.^{2,9} A selective inversion pulse can be obtained by using a relatively long, low power pulse. However for those spectrometers which lack the facility to produce low power pulses, selective inversion can also be obtained by using hard pulses in the DANTE sequence¹⁰ or

by using a shortened one-dimensional (1D) version of the two-dimensional (2D) exchange experiment, which is described in Section 2.3. In the latter case the pulse sequence is: $\pi/2_x - t_1 - \pi/2_x$, where $t_1 = \frac{1}{2}\Delta\nu$ and $\Delta\nu$ is the difference in resonance frequencies of the A and B spins. If the transmitter frequency is set to the resonant frequency of the A spin then at the end of this sequence the A magnetization will lie along the $-z$ axis while the B magnetization is returned to the $+z$ axis.¹¹

2.2 Selective Saturation

If the B spin is selectively irradiated (such that $M_B = 0$ at $t = 0$) for a time, t , then the observed intensity of the A resonance decays with a time constant $\rho_A + k_{+1}$ and reaches a new equilibrium value:

$$M_{(t=\infty)}^A = \frac{\rho_A M_0^A}{(\rho_A + k_{+1})} \quad (9)$$

Thus both ρ_A and k_{+1} can be calculated. The saturation pulse can be generated either by using a long, low power pulse or by using hard pulses in the DANTE sequence. Although instantaneous saturation is incompatible with the mechanism of saturation, it can be approximated by using a relatively large irradiating field strength.¹² The limit imposed on the amplitude of the saturating field is set by the requirement that the saturating pulse should be selective. Too large a saturating field will result in nonspecific saturation of the observed resonance leading to decreases in its steady-state magnetization (M_{∞}^A) and apparent spin-lattice relaxation time.¹³ Both effects will lead to an overestimation of the exchange rate. This experiment, which is sometimes referred to as the time-dependent saturation transfer experiment, has two variants which have also been used to measure enzyme-catalyzed exchange. In these experiments the steady state and equilibrium magnetizations of the nonirradiated spin ($M_{(t=\infty)}^A$ and M_0^A , respectively) are measured in order to obtain the ratio $\rho_A/(\rho_A + k_{+1})$ [see equation (9)]. The sum, $(\rho_A + k_{+1})$ is then determined in separate experiments by measuring the z magnetization of the A spin following either its inversion or saturation in the presence of saturation of the B spin. The A magnetization relaxes exponentially toward its steady-state value ($M_{(t=\infty)}^A$) with a time constant $(\rho_A + k_{+1})$. The relative accuracy of the kinetic parameters derived from these experiments in a given amount of time have been compared using simulated data.¹⁴ The choice of which particular saturation transfer experiment to use depends on the rate constant to be measured and the T_1 of the observed resonance.

2.3 Two-Dimensional Exchange Experiments

The two-dimensional exchange experiment introduced by Jeener et al.¹⁵ uses the following pulse sequence: $\pi/2 - t_1 - \pi/2 - t_m - \pi/2 - t_2$. The first two pulses frequency label the z magnetization. Transfer of this magnetization between the A and B spins due to cross relaxation or chemical exchange during the t_m period is then detected during the t_2 period following the third 90° pulse. These signals are recorded for regular increments of t_1 and the resulting matrix of free

induction decays is then double Fourier transformed to produce a 2D spectrum. Magnetization that has exchanged between the A and B sites will appear as cross peaks while the diagonal peaks represent magnetization which has failed to migrate. Cross peaks arising from coherent magnetization transfer due to scalar coupling are eliminated by phase cycling the pulses.¹⁶ The amplitudes of the peaks in the 2D spectrum are described by equations similar to those that describe signal intensities in the selective inversion experiment.⁷ In early applications of the technique the exchange rate constants were estimated by recording 2D spectra at a series of t_m values and fitting the observed cross-peak intensities versus t_m to the appropriate exchange equation. Alternatively the rate constants can be estimated from the initial rate of cross-peak buildup, which is equal to k_{+1} (or k_{-1}). Recording a series of 2D spectra is extremely time consuming and therefore a method of analysis was developed to determine the rate constants from a single 2D exchange spectrum.

The 2D spectrum can be described by the following equation:

$$\mathbf{M} = \exp(\mathbf{R}t_m)\mathbf{M}_0 \quad (10)$$

where $\mathbf{M}$ is a matrix comprising the peak volumes in the spectrum and $\mathbf{R}$ is the matrix of exchange and relaxation rate constants. For the simple two-site exchange system described above, $\mathbf{R}$ has the form:

$$\mathbf{R} = - \begin{bmatrix} \rho_A + k_{+1} & -k_{-1} \\ -k_{+1} & \rho_B + k_{-1} \end{bmatrix} \quad (11)$$

$\mathbf{M}_0$ is a diagonal matrix representing the 2D spectrum obtained with $t_m = 0$. This is usually replaced with $\alpha\mathbf{S}_0$, where $\mathbf{S}_0$ is the diagonal matrix of mole fractions obtained from a fully relaxed 1D experiment and α is an unknown scaling factor. Replacing $\mathbf{M}_0$ with $\alpha\mathbf{S}_0$, which avoids collecting another 2D spectrum, gives rise to false values for the diagonal elements in the $\mathbf{R}$ matrix but leaves the off-diagonal elements, which specify the exchange rate constants, unaffected. This method, which has been termed 'back transformation'^{17,18} and a 1D counterpart derived from it,¹⁹ essentially involve fitting an exponential function to a data set consisting of only two time points. These are the magnetizations (signal intensities) of the exchanging species when $t_m = 0$ and when t_m is set at some other value. The value of t_m which will give the most precise estimate of the exchange rate constants, has been estimated to be equal to $1/(R + k)$, where R and k are the mean values of the relaxation and exchange rate constants, respectively.²⁰ The back transformation method has been used to estimate the exchange rate constants in the reactions catalyzed by adenylate kinase and phosphoglycerate mutase in vitro.²¹

Exchange rate constants can also be obtained from a single 2D exchange spectrum by using the 'accordion' experiment described by Bodenhausen and Ernst.²² This is a modification of the 2D experiment in which the t_m period is incremented in steps of t_1 and the rate constants are obtained by analysis of the lineshapes in the resulting 2D spectrum. If, in the two-site exchange system discussed above, ρ_A and ρ_B and the concentrations of the A and B spins are equal then the diagonal peaks in the accordion spectrum will have a lineshape which is given by the sum of two Lorentzian lines with linewidths ρ and $(k_{+1} + k_{-1} + \rho)$ while the cross-peak lineshapes are given

by the difference between these two Lorentzian lines. This analysis of the accordion experiment was used to estimate the exchange rate constants in the reaction catalyzed by creatine kinase *in vitro*.²³ Analysis of the accordion experiment in a more typical case, where the populations of the exchanging spins are unequal and the relaxation rate constants are different has been considered by Kuchel.⁷

2.4 Comparison of 1D and 2D Methods

Two-dimensional methods have the advantage that in multisite exchange systems they can, in principle, detect all the exchanges in a single experiment. The 2D exchange experiment and its 1D counterpart also have the advantage that they use nonselective pulses and therefore avoid the problems associated with the limited selectivity of the irradiating field in the 1D experiments. All the methods described require some preliminary estimate of the exchange rate constant in order to optimize the experimental protocol, for example to choose the optimal t_m in the 2D experiments or the optimal saturation transfer protocol in the 1D experiments. For experiments *in vivo*, where limited sample viability precludes long data acquisition times, the 1D methods are preferred over the more time consuming 2D methods. This is reflected in the fact that although 2D exchange experiments have been performed,²⁴ the overwhelming majority of magnetization transfer measurements *in vivo* have employed 1D methods.

2.5 Effect of the Equilibrium Constant on Exchange Measurements

In the selective inversion and 2D experiments, which follow the z magnetization of the exchanging species after a transient perturbation, the amplitude of these changes depends on the mole fractions of both species. This is illustrated by equation (7) for the inversion transfer experiment. This is not the case in a saturation transfer experiment in which changes in the z magnetization of the A spin are independent of the concentration of the B spin [see equation (9)]. Thus a saturation transfer experiment may detect exchange between a metabolite present in high concentration and one present in low concentration, even if the latter is so low in concentration as to be undetectable in the NMR spectrum. This is illustrated by the saturation transfer spectra, obtained from the dog heart *in vivo*, shown in Figure 1. Saturation of the γ -phosphate resonance of ATP also results in saturation of the β -phosphate resonance of adenosine diphosphate (ADP), which is less than 1 ppm upfield and which is too low in concentration to be observable in these spectra. Exchange between the β -phosphate of ADP and the β -phosphate of ATP results in a decrease in the resonance intensity of the latter. The lower limit on the concentration of the metabolite to which flux can be measured is imposed by the amount of power required to achieve saturation of the nucleus in this site. For any given flux, as the concentration of the metabolite is decreased the residence time of the nucleus in this site will also decrease and the irradiating field required to achieve its saturation will increase. This was demonstrated experimentally with a study of ATP–ADP exchange catalyzed by creatine kinase *in vitro*.²⁵

Figure 1 ^{31}P NMR saturation transfer spectra of the dog heart *in vivo*. The spectra were acquired using a surface coil placed over the heart. Saturation of the γ -phosphate resonance of ATP results in transfer of magnetization to the phosphocreatine and P_i resonances. This is manifest as a decrease in their resonance intensities [compare spectra (a) and (b)], which is clearly seen in the difference spectrum (c). The decrease in the β -phosphate resonance of ATP is due to exchange between ADP and ATP (see text). The decrease in the α -phosphate resonance, which has also been observed in a number of other studies and which cannot be explained by the lack of selectivity of the saturating field, is unexplained. Abbreviations: PDE, phosphodiester; PCr, phosphocreatine; γ -ATP, γ -phosphate resonance of ATP; α -ATP, α -phosphate resonance of ATP; β -ATP, β -phosphate resonance of ATP. Commun.*, 1988, **151**, 70)

2.6 Assumptions Made in Analyzing Magnetization Transfer Data

2.6.1 Two-Site Exchange

Magnetization transfer measurements of exchange between two substrates in an enzyme-catalyzed reaction are frequently

analyzed using the two-site exchange model described above. Enzyme-bound intermediates in the exchange reaction, which in general will be very low in concentration compared with the free substrates and therefore turning over very rapidly, can usually be ignored. However an intermediate could affect the measured exchange velocity if there was rapid loss of the magnetic label at this site, i.e. if the T_1 of the exchanging nucleus in this site were very short. Although modeling studies have shown that the T_1 would have to be very short,²⁵ and there appears to be no evidence for this from ^{31}P NMR studies of enzyme-bound substrates, there are now two independent reports that indicate that this may occur in the exchange between ATP and ADP catalyzed by creatine kinase in vitro.^{25,26} These compared isotope exchange measurements with magnetization transfer measurements and showed that under some conditions the latter underestimated the exchange rate. However it should be emphasized that for the exchange most often measured in vivo, i.e. that between phosphocreatine and ATP, there was good agreement between the isotope exchange and magnetization transfer data.

2.6.2 Relationship Between Measured Exchange and Net Flux

Since the magnetization transfer experiment, like an isotope exchange experiment, only measures exchange between a pair of substrates there need be no direct relationship between this exchange flux and the metabolically relevant net flux catalyzed by the enzyme. Consider, for example, the reaction mechanism of creatine kinase, which is illustrated in Figure 2. Magnetization transfer measurements of exchange between ATP and ADP and between phosphocreatine and ATP and isotopic measurements of exchange between ATP and ADP, between PCr and ATP and between PCr and Cr have been shown to be similar under most conditions, consistent with rate-limiting interconversion of the two ternary complexes (E.MgADP.PCr and E.MgATP.Cr).^{25,26} Therefore under these conditions it is valid to equate magnetization transfer measurements of PCr $\leftrightarrow$ ATP exchange with net flux in the reaction since the same step, the interconversion of the ternary complexes, is rate-limiting for all the exchanges and for the net flux catalyzed by the enzyme. However at high [PCr]/[Cr] ratios (above 2) the ATP $\leftrightarrow$ PCr exchange flux exceeds the ADP $\leftrightarrow$ ATP exchange flux, indicating that control has shifted from the interconversion of the ternary complexes to the steps of substrate–enzyme complex formation and breakdown.

Magnetization transfer measurements of steady-state ATP turnover appear to be measuring net flux. The evidence for this has come from the correspondence between P:O ratios

(moles of ATP synthesized: atoms of oxygen consumed) measured in the cell with those measured in suspensions of isolated mitochondria catalyzing net ATP synthesis (discussed in Section 3.2). However, evidence has been obtained recently that mitochondria in vivo can catalyze an ATP $\leftrightarrow$ Pi exchange reaction under some conditions.

3 FLUXES MEASURED IN VIVO

3.1 Creatine Kinase

Creatine kinase catalyses the reaction:

The enzyme is abundant in muscle and neural tissue, where the reaction is normally near-to-equilibrium.²⁷ When an energy demand is placed on the tissue, the ATP concentration is maintained at the expense of phosphocreatine. Phosphocreatine thus acts as an energy store, buffering temporal changes in the ATP and ADP concentrations.

3.1.1 The Shuttle Hypothesis

A second role for the enzyme has been proposed based on the observation that the enzyme is spatially localized (reviewed by Wallimann et al.²⁷). For example in muscle, concentrations of the enzyme are found at the myofibrils and at the mitochondria. In the latter case there is a distinct mitochondrial isoform which is located in the intermembrane space. According to the ‘shuttle hypothesis’ phosphocreatine also acts as a spatial energy buffer, shuttling energy between the sites of production, the mitochondria, to the sites of utilization, in muscle the myofibrillar Mg^{2+} -ATPase. In its simplest form phosphocreatine and creatine are thought to act as parallel diffusion pathways for the diffusion of ATP and ADP, respectively, between the mitochondria and myofibrils.²⁸ More elaborate models take into account the apparent functional interactions between the enzyme and other proteins in the muscle. For example there is good evidence that the mitochondrial isoform interacts directly with the adenine nucleotide translocase in the inner mitochondrial membrane, resulting in channeling of mitochondrially-generated ATP between the two proteins.²⁷ Inevitably ^{31}P NMR magnetization transfer measurements of creatine kinase kinetics in vivo have been used to look for evidence of the shuttle.

Studies in the perfused heart, which showed an increase in the reaction velocity with increased ATP turnover despite only small changes in the enzyme’s steady state substrate concentrations, indicated a discrepancy with the solution properties of the enzyme.^{29,30} A similar increase in creatine kinase flux with increased ATP turnover has also been observed in brain.³¹ Measurements in neonatal rabbit hearts, at different stages of development, showed that the reaction velocity increased as the concentration of the mitochondrial isoform increased,³² a result which is consistent with the shuttle hypothesis and with functional coupling between the mitochondrial isoform and the adenine nucleotide translocase. This study also showed, as expected from the solution properties of the enzyme, that flux increased with the increase

Figure 2 Reaction mechanism of creatine kinase. E represents free enzyme; PCr represents phosphocreatine and Cr represents creatine; MgADP and MgATP represent the Mg^{2+} -bound forms of ADP and ATP respectively

in creatine and phosphocreatine contents that occurred during development. These data may explain why in skeletal muscle, which contains only 2% mitochondrial creatine kinase activity, there is no increase in creatine kinase reaction velocity with increased work.^{33,34} Further evidence for compartmentation of creatine kinase came from the observation that in a time-dependent saturation transfer experiment the decay of the phosphocreatine resonance was not always a single exponential. A kinetic model developed to explain these data attributed this to a nonsaturable mitochondrial pool of ATP in exchange with phosphocreatine in the reaction catalyzed by the mitochondrial isoform.³⁵ More recent work in the heart has shown that the presence of the mitochondrial isoform is not a prerequisite for the increase in creatine kinase flux with work. Increased flux was shown to result from changes in the enzyme's substrate concentrations. However there was, in addition, an unexplained change in the kinetic properties of the enzyme between rest and work.³⁶

The role of creatine kinase in the shuttle has also been investigated by feeding animals creatine analogs which accumulate in cardiac and skeletal muscle and which inhibit the enzyme.^{37,38} Magnetization transfer measurements of creatine kinase fluxes in these muscles, which were less than or comparable to the ATP turnover rates, showed that phosphocreatine could not be an obligatory intermediate in energy transduction. However it is now clear that during the long feeding periods required, skeletal muscle undergoes compensatory metabolic adaptations.³⁹ Furthermore in heart, it was subsequently shown that the presence of a creatine analog does in fact impair muscle function.⁴⁰

Further information about the role of creatine kinase in muscle function will undoubtedly come from using NMR magnetization transfer techniques in conjunction with molecular genetic methods for manipulating the tissue concentrations of the enzyme. For example the role of the different isoforms in muscle function is being investigated by changing their expression in the skeletal muscle of transgenic mice.⁴¹ Elimination of the M isozyme, using gene targeting techniques, was shown totally to eliminate magnetization transfer between phosphocreatine and ATP.⁴² Remarkably the phosphocreatine levels declined normally during exercise. Presumably this was due to the residual mitochondrial creatine kinase activity present. Interestingly the muscle adapted to the absence of the M isoform and these adaptations show some similarities to those observed in muscle of analog-fed animals.

3.1.2 Differences in the Forward and Reverse Fluxes

Despite the fact that the reaction catalyzed by creatine kinase is normally near-to-equilibrium there have been numerous magnetization transfer studies which have shown that the forward and reverse fluxes are unequal. Two models have been proposed to explain this difference. One proposes that there are two pools of ATP, a large pool and a small pool which are both in exchange with phosphocreatine. Saturation of the observed γ -phosphate resonance of ATP allows measurement of flux from phosphocreatine to both pools of ATP. However the converse is not true since saturation of the phosphocreatine resonance will result in flux being measured predominantly between the large ATP pool and phosphocreatine. This model was elaborated in terms of the shuttle hypothesis, where the cytosolic ATP pool constitutes the large pool and the small

pool is represented by ATP in the mitochondria and at the myofibrils.⁴³ In support of this proposal it was shown that the discrepancies in the forward and reverse fluxes reported in the literature increased as the rate of ATP synthesis increased. It was also pointed out that the forward and reverse fluxes measured in rat brain were equal if measured using a 2D exchange experiment but were unequal if measured using a saturation transfer experiment. As pointed out above, the saturation transfer experiment is capable of measuring exchange between metabolites present in very unequal concentrations whereas in a 2D exchange experiment, both exchanging pools need to be present at a significant concentration for the exchange to be observed. The second model considers the difference in the fluxes to be due to the fact that the γ -phosphate of ATP is in exchange with Pi as well as with phosphocreatine. Thus while exchange measurements of the flux from phosphocreatine to ATP can be analyzed using a two-site exchange model the reverse flux may be underestimated if not treated as a three-site exchange system, i.e. $\text{PCr} \leftrightarrow \text{ATP} \leftrightarrow \text{Pi}$. Much of the evidence which supports a compartmentation model is also compatible with this model (discussed by Brindle⁶). For example the difference in creatine kinase fluxes in this model would be expected to increase as the rate of $\text{ATP} \leftrightarrow \text{Pi}$ exchange increases. The elegant study of Ugurbil et al.⁴⁴ on the perfused working rat heart appeared to provide an answer as to which model was correct when it was shown that the forward and reverse fluxes were equal if the reverse flux was measured by saturating both the phosphocreatine and Pi resonances and employing a three-site exchange model for data analysis. However there are two problems with this experiment. As Ugurbil et al.⁴⁴ point out, the fractional reduction in the γ -phosphate resonance of ATP, when both the phosphocreatine and Pi resonances are saturated, should be equal to or less than the value observed when only the phosphocreatine resonance is saturated. This was not the case under one set of perfusion conditions. Another problem is that the measured $\text{ATP} \leftrightarrow \text{Pi}$ exchange is simply not fast enough to give the observed discrepancy.⁴⁵ An early study, which showed a difference in the forward and reverse fluxes despite the application of a correction factor which allowed for the observed exchange between ATP and Pi, concluded that the γ -phosphate of ATP must be in rapid exchange with other sites.⁴⁶

There appears at present to be no completely satisfactory explanation for the discrepancy in the forward and reverse fluxes. However, in the context of compartmentation, perhaps tissue heterogeneity should also be considered. For example, in skeletal muscle measurements of enzyme levels in individual fibers have shown extreme heterogeneity, even between adjacent fibers.⁴⁷

3.2 ATP Turnover

A significant limitation of magnetization transfer measurements *in vivo* is that very few enzyme-catalyzed fluxes are measurable. For example the spectra shown in Figure 1 illustrate almost all the exchanges that can be measured using ³¹P NMR magnetization transfer measurements *in vivo*. However, in measuring the fluxes between Pi and ATP the technique can be used to determine arguably the most important fluxes in a living cell, ATP synthesis and hydrolysis. In early measurements of the flux between Pi and ATP it

was assumed that the flux was catalyzed solely by the mitochondrial F_1F_0 ATP synthase. However subsequent studies, in a number of systems including *E. coli*, yeast and the perfused heart, demonstrated that the coupled reaction catalyzed by the glycolytic enzymes, glyceraldehyde 3-phosphate dehydrogenase (GAPDH) and phosphoglycerate kinase (PGK) could also participate in this exchange reaction (reviewed by Brindle⁶). Elimination of this glycolytic exchange allows the $P_i \leftrightarrow$ ATP exchange catalyzed by the mitochondria to be determined. For example, a detailed study of $P_i \rightarrow$ ATP and $ATP \rightarrow P_i$ fluxes in the perfused rat heart, in which the glycolytic exchange was inhibited, either by iodoacetate treatment or by depletion of glycolytic intermediates, showed that the P:O ratio was approximately 2.4.⁴⁸ The similarity of this value to that displayed by isolated mitochondria in vitro catalyzing net ATP synthesis suggests that the mitochondrial ATP synthase is operating unidirectionally in vivo and that the technique measures net ATP turnover. The technique can thus be used to assess the degree of mitochondrial coupling in vivo. For example measurements of P:O ratios in the postischemic perfused rat heart showed that mitochondrial uncoupling, which would lead to a decrease in the measured P:O ratio, could not be the cause of the observed postischemic depression in mechanical function.⁴⁹

The measurements of $P_i \rightarrow$ ATP flux have also been used to examine the properties of the glycolytic enzymes. Studies of the perfused rat heart⁴⁹ and the dog heart in vivo⁵⁰ have shown that the activities of GAPDH and PGK are altered in the postischemic myocardium. Measurements of $P_i \rightarrow$ ATP flux in yeast cells, in which the concentration of PGK had been increased using molecular genetic techniques, allowed a detailed study of the kinetic properties of this enzyme in the intact cell. This showed that there were no unusual kinetic properties conferred on the enzyme by its cellular environment.⁵¹

Although the glycolytic exchange reaction can compromise magnetization transfer measurements of ATP turnover, particularly in the presence of glucose, this may be less of a problem in vivo. For example the glycolytic contribution to the measured $P_i \rightarrow$ ATP flux in the postischemic dog heart in vivo appeared to be much lower than that observed in postischemic glucose-perfused rat hearts.^{49,50} In rat skeletal muscle in vivo, the measured $P_i \rightarrow$ ATP flux correlated well with the work performed. Although a glycolytic contribution could not be rigorously excluded the measured flux showed good agreement with ATP turnover rates estimated from oxygen consumption measurements in the perfused hind limb and the rates of phosphocreatine breakdown during a tetanus.³⁴

Recent studies on yeast have shown that the measured $P_i \rightarrow$ ATP flux is increased in cells which have been genetically modified to overexpress an isoform of the mitochondrial adenine nucleotide translocase.⁵⁵ This increase in flux, which occurred in the absence of an increase in oxygen consumption, suggested that the mitochondria were catalysing predominantly an $ATP \leftrightarrow P_i$ exchange reaction under these conditions rather than net ATP synthesis. This interpretation of the data is in accord with an earlier radioisotope study of $ATP \leftrightarrow P_i$ exchange in isolated mammalian mitochondria which showed that, at low rates of respiration, mitochondria can catalyze an $ATP \leftrightarrow P_i$ exchange, but that at higher rates of respiration the $P_i \rightarrow$ ATP flux becomes unidirectional. Thus it is possible that in mammalian systems at low rates of respiration, even when

the glycolytic contribution has been removed, the $P_i \rightarrow$ ATP flux measured in a magnetization transfer experiment might include some contribution from a mitochondrially catalyzed $ATP \leftrightarrow P_i$ exchange.

4 CONCLUDING REMARKS

An interesting area, which I have not covered, is measurements of membrane transport (reviewed by Kuchel⁷). Of particular interest is a ^{19}F NMR study of 3-fluoro-3-deoxy-D-glucose transport across the red cell membrane.⁵² However it is not yet clear whether this technique can be applied in other systems. Another interesting study employed the ^{31}P NMR saturation transfer experiment to measure $ATP \leftrightarrow$ ADP exchange across the membrane of isolated mitochondria.⁵³ This showed that the exchange rates were more than 10 times faster than the rates previously determined using isotopic techniques and that they were almost 10 times faster than the ATP synthase ($ATP \leftrightarrow P_i$) exchange rates.

I have concentrated on ^{31}P NMR magnetization transfer measurements in vivo as this reflects my own interest, an interest which was initially stimulated by the potential of the technique to provide unique information on the kinetic properties of enzymes in vivo.

1 INTRODUCTION

The pioneering work of Wüthrich and co-workers on structure determination of bovine pancreatic trypsin inhibitor using NMR methods generated a great deal of excitement in the NMR and biochemical communities in the early 1980s.¹ This occurred partly because the work offered the prospect of protein structure elucidation in aqueous solution as opposed to in the confines of a crystalline environment. With successful application following successful application, however, there was a tendency to forget that a basic tenet of the early methodology imposed crystal-like constraints on structures which could have experienced much greater conformational flexibility in an aqueous environment. More precisely, the cross relaxation, or NOE data on which NMR structures were based were interpreted using a rigid, isotropically tumbling model for the protein in question. This model leads to the often quoted $1/r^6$ relationship between cross relaxation rates and internuclear distances r . We now know that this model is violated frequently, and, in retrospect, it may even seem surprising that the NMR structures determined show the quality and accuracy that they do. Some insight into the effects of violating the rigid model assumption, and the reasons why violation has made relatively little difference to the quality of many NMR structures is offered through our experiences with the structure determination of a protein that seems to have more than its fair share of motional freedom, acyl carrier protein (ACP).

ACP is a small protein (about 80 amino acids) which is found as a part of the fatty acid synthetase systems of most organisms.² It participates at many stages of lipid biosynthesis as a carrier of fatty acyl chains during the course of their elongation and modification. Despite the fact that it has been studied for more than 20 years, and in organisms such as *Escherichia coli* is among the most abundant proteins, no crystal structure had been produced at the point when NMR structural methods came on the scene, nor has a crystal structure been produced at the time of writing. Perhaps the very diverse class of interactions required of this protein, or the very long history of difficulties in producing isomorphous

replacements for crystal studies, should have suggested a protein with more than a normal level of motional freedom. Perhaps some structural variability should have been suggested by the absence of disulfide bonds and the relatively high net negative charge on this small protein. Nevertheless, with so many successes in NMR structure determination of other small proteins, an attempt at an NMR structure for ACP seemed reasonable.

2 EFFECTS OF RAPID INTERNAL MOTIONS

There actually are some reasons to believe that certain classes of internal motions in proteins may not lead to severe violation of a rigid model. Motions which fall into this class include some of the very rapid motions produced by the cumulative effects of oscillations about bonds interconnecting proton pairs. In 1988, LeMaster et al.³ introduced the simple model shown in Figure 1 in an attempt to illustrate the effects of these motions. The two protons are meant to move within the spheres in an uncorrelated fashion, sampling a centrosymmetric distribution on a timescale very short compared with that which dominates the cross-relaxation process (usually the timescale of protein tumbling). Under these conditions the dipolar interactions between the protons will be partially averaged. The averaging includes two terms, a distance term ($1/r^3$) and an angular term ($Y_0^2(\theta)$). These terms enter as a product in the spectral density function dominating cross relaxation. It is obvious that the first term will tend to increase with motion, since close distances of approach are weighted more heavily, and the second term will decrease as wider ranges of angles are sampled. What is not obvious is that the two terms exactly cancel for this very simple model, and relaxation effects prove to be identical to those for a rigid model with protons fixed at the centers of the spherical distributions. To the extent that internal motions are rapid, centrosymmetric, and uncorrelated, this may explain why a rigid model analysis works well in so many cases. Dynamics simulations based on works such as that of Kuriyan et al.⁴ suggest that many internal motions approach this limit.

3 EFFECTS OF SLOWER INTERNAL MOTIONS

Unfortunately, not all internal motions fall into the category discussed above, and effects of these motions on

Figure 1 A simple model for rapid internal motions in proteins. Protons H_A and H_B move randomly in an uncorrelated fashion within their respective spheres

Figure 2 A simple model for slow internal motions in protein with a representation of penalty functions used as distance constraints

the interpretation of NOE data can be severe. Consider the limit in which internal motions are slow compared with overall tumbling of the protein. The motions do not then contribute to averaging of the dipolar interaction itself, but result in averaging of cross-relaxation effects experienced in the conformations sampled. In the absence of other motions, the cross-relaxation effects contribute in proportion to $1/r^6$. This strong distance dependence leads to dramatic effects.

Consider the case depicted in Figure 2. Two protons, A and B are fixed at a separation of 0.9 nm in all states sampled. Proton C finds itself 0.3 nm from A and 0.6 nm from B in one state, and 0.6 nm from A and 0.3 nm from B in another state. The two states are equally populated and interconversion between the states is sufficiently rapid to give rise to a single set of NMR resonances and NOE connectivities. NOEs between C and A and C and B will both be seen. The C–A NOE will be dominated by the first state and will have approximately 51% of the NOE that would have arisen if only the first state had been occupied. Similarly, the C–B NOE will be dominated by the second state and will have 51% of the NOE that would have arisen if only the second state had been occupied. If these NOEs were interpreted as if a single rigid state had existed, we would conclude that C is 0.336 nm from A and C is 0.336 nm from B. Since A and B are 0.9 nm apart, this is geometrically impossible. In searching for structures which satisfy a set of such averaged NOEs, we would either find that structures always violated some subset of NOEs, or distances corresponding to the 0.9 nm molecular constraint would be severely distorted producing high energy structures. This is the type of evidence for motion we initially found for ACP.

4 INITIAL WORK ON ACYL CARRIER PROTEIN

Initial work on ACP produced structures with substantial violations of NOE constraints in all cases.⁵ The fact that these were so noticeable was in part due to the manner in which distance constraints were introduced. A penalty function (or pseudoenergy term) representing a constraint was added to the force field of a widely available molecular mechanics/molecular dynamics program and a search was executed for structures which simultaneously yielded low

molecular energies and minimum penalties due to violation of NOE constraints.

The form of the penalty function was chosen to mimic more closely a true error function than the harmonic constraints commonly used at the time. In principle, the penalty function would be the square of the difference between a measured NOE [or $1/r^6(\text{exp})$] and a NOE calculated from a trial structure [or $1/r^6(\text{cal})$]. To improve convergence properties, a slightly modified form of this ideal penalty function was used. As illustrated in Figure 2, these penalty functions are highly asymmetric, rising abruptly when distances in trial structures are shorter than distances predicted from NOEs, and rising more slowly to a plateau when distances in trial structures are longer than distances predicted from NOEs. In the case of conflicting constraints, summation of these terms leads to double minimum functions in a way that harmonic constraints cannot. Searches then produce structures that tend to satisfy only one of the conflicting constraints at a time, leaving a large violation for the other constraints. Harmonic, or square well, constraints tend to produce structures that converge to a single distorted structure, with moderate violations of all constraints in a conflicting set.

Approaches using both harmonic constraints and highly asymmetric constraints were both used on ACP data.^{5,6} Qualitatively similar structures were actually produced: three nearly parallel α -helices are observed with a very large loop connecting antiparallel helices I and II and a smaller loop connecting parallel helices II and III. The prosthetic group carrying the acyl chain is connected near the beginning of helix II, and acyl chains, when present, appear to lie between helices II and III.⁷ Initially, we were fascinated with the opportunity to examine structures for ACP, and ignored the fact that the structures did not converge very well, especially with the more realistic penalty function (0.2–0.3 nm rms deviation of backbone atoms from the corresponding atoms of an average structure). On careful examination, however, the pattern of alternate violation of different NOEs was easily observed and the initial suggestion of a violation of the rigid model was made.⁵

5 A TWO-STATE MODEL FOR ACYL CARRIER PROTEIN

Dealing simultaneously with the effects of motion and structure on NOE values is a problem that is likely to recur as a wider variety of protein systems are studied. A first attempt to do this was made in the case of ACP. The penalty function approach mentioned above is easily generalized to the case where NOEs represent the average of NOEs seen in discrete structures. One simply replaces the calculated $1/r^6$ from a single trial structure with the average of $1/r^6$ from a pair of trial structures. During a search, pairs of structures whose average characteristics satisfy experimental observation are then produced. With limited NOE data and computational resources at the time, an exhaustive search could not be conducted, but using pairs of structures produced using a rigid model and minimizing these pairs with appropriate penalty functions, it was shown that structures with substantially reduced NOE distance violations and greatly improved molecular energies could be produced.⁸

Figure 3 Backbone structures for two states sampled by ACP. Structures are based on 450 NOE constraints and 66 coupling constant constraints

Structures for one such pair are shown in Figure 3. These are from structures produced after further refinement using coupling constant data.⁹ Structure B is energetically the more favorable and clearly shows the three helices mentioned above. The second structure (E) maintains a similar overall fold, but positioning of loops differs significantly and there is clear disruption of some of the helical structure, particularly that of helix II. At this point there was really no reason to believe that two and only two structures should contribute. Each may therefore represent the average of two or more structures and there is no reason to believe that either should have an absolutely ideal geometry.

6 SUPPORTING EVIDENCE FOR A MULTIPLE STATE MODEL

The search for supporting evidence for multiple conformations of ACP has occupied a good deal of time. The initial suggestion was not based on particularly strong evidence. Discrete resonances for different forms of *E. coli* ACP were not observed, only a single set of averaged resonances. It is also true that misassignment of some resonances could produce incompatibilities of NOE constraints in much the same way as occurs on averaging among conformational forms. Thus, a search for alternate explanations continues. Some support for multiple conformations has, however, come from data on ACPs from other species. ACP-I from spinach provides one piece of evidence for multiple conformations. In this case, a pair of resonances is seen for many of the assignable sites in the protein. These pairs are particularly noticeable in acylated forms of the protein, but also appear as major and minor components in nonacylated forms.¹⁰ It has been possible in the nonacylated form of spinach ACP-I to show using ROESY that the pairs of resonances are not due to chemical heterogeneity but arise from conformational forms interconverting on the order of 1 s^{-1} .¹¹

Direct support for multiple conformations for *E. coli* ACP has not been found, nor have conditions which clearly stabilize a single conformational form. Addition of divalent cations does stabilize the protein to thermal denaturation;^{12,13} however, no improvements in structure have yet been realized. It is, however, interesting to note that during thermal denaturation of *E. coli* ACP, conditions can be selected under which

either slow exchange, where discrete resonance for native and denatured forms are observed, or fast exchange, where a single set of averaged resonances are observed, exists.¹³ The fast exchange situation is perhaps a little unusual for denaturation of a protein. But this situation does occur for *E. coli* ACP under the conditions of high levels of monovalent salts, where most of the initial structural data were collected.

Indirect support for the multiple state model has also come from attempts to monitor the stability of various helical structural elements. Clearly the model suggested in Figure 3 would require less than normal stability, at least for helix II. The use of amide proton exchange rates to monitor the stability of secondary structural elements is now well established.¹⁴ Exchange of native protons for solvent deuteriums when a sample is freshly dissolved in $^2\text{H}_2\text{O}$ is believed to be precluded as long as amide protons are involved in hydrogen-bonding networks of common secondary structural elements. Under conditions where the base catalyzed rate of exchange in the open form of a structural element is slow compared with the rate of reformation of the structural element, rates corrected for variations in the base catalyzed exchange step provide a direct measure of the thermodynamic stability of the element.

The advent of extremely efficient methods for the collection of ^{15}N - ^1H correlated experiments has provided an ideal means of monitoring amide exchange rates.¹⁵ Figure 4 shows a comparison of amide exchange rates for sites in helix I, residues 3–15, and helix II, residues 36–50.¹⁶ The timescales are adjusted to remove effects of variations in intrinsic rates for all except Glu-13. It is clear, first of all, that exchange of amide protons in ACP helices is relatively fast. Rates seen in other α -helical proteins of similar size are often more than an

Figure 4 Loss of signal intensity of individual peaks for amide groups in a ^1H - ^{15}N HSQC spectrum. Times are scaled relative to those of Glu-13 using the intrinsic exchange rate data of Molday et al.²³ The sample was approximately 3 mM ACP, 10 mM Ca^{2+} , pH 6.0; acquisition required 7 min per two-dimensional spectrum

order of magnitude slower. Second, exchange for residues in helix II is especially fast. Thus, it appears reasonable that ACP is a molecule with an unusual level of internal motion and that it is likely that multiple conformational states contribute to the NOEs measured in the course of structure determination.

ACP is of course not unique in having multiple conformational states and showing equilibration between them. Several examples of slow exchange among conformational forms are documented in the literature.^{15,17,18} These cases are easily identified because of the appearance of discrete pairs of resonances for one or more chemically distinct sites in the protein. However, there is no reason to believe that there is anything less than a continuum of timescales for interconversion of conformational forms, and that there are numerous examples of fast exchange among conformational forms for which detection is less straightforward.

7 OVERVIEW

The need for dealing with structure determination in the presence of a variety of motional timescales has not gone unnoticed. Of a number of methods for dealing with the effects of motion on structural parameters, I will mention just a few. First, there is the time averaged constraint algorithm of Torda et al.^{19,20} This algorithm uses molecular dynamics to sample different states, and averages over a characteristic decay time to generate a time averaged penalty function that can help direct the conformational search. It has been implemented for both NOE and coupling constant derived constraints. The algorithms are probably most applicable to the effects of motions on shorter timescales.

Second, there is a broadly based multiple conformation search algorithm proposed by Brüschweiler and co-workers.²¹ This is based on identifying structures that satisfy subsets of distance constraints, and then combining the structures in pairs, triples, etc., to reproduce all NOE data. As yet, this has been applied only to relatively small systems, but it is applicable to motions which are too slow to deal with using molecular dynamics based algorithms. Finally, there are experimental approaches that can eliminate certain classes of exchange contributions to measured NOEs. These approaches have been described by Fejzo et al.²² and have been applied to the case where motion is slow enough to yield discrete resonances.

In summary, a search for a three-dimensional structure of ACP carrier protein has been fruitful in that a first picture of this important carrier of acyl chains has been produced. Although it is relatively low in resolution, the picture provides a basis for understanding acyl chain interactions and protein-protein interactions that are fundamental to lipid biosynthesis. The search has, however, also brought to light the need to consider internal motions of proteins and the possible effects these motions might have on structures deduced from NMR data. It is obvious that the effects of motion on interpretation of NOE data are being increasingly considered and that methods which may provide alternative means of interpretation are likely to evolve in the future.

1 INTRODUCTION

Proteases are enzymes that catalyze the cleavage of peptide bonds in proteins [equation (1)]. The biological roles of proteases are incredibly diverse: they are essential to all processes that characterize a living organism, from its inception as an independent entity to the degradations of its tissues after death. Because their study has a long history, various nomenclatures have developed. The general terms protease, peptidase, peptide hydrolase, proteolytic enzyme, and proteinase are used interchangeably, although not always correctly so.

A wide variety of proteases have been isolated and characterized. Some proteases have specificity for cleaving the amino acid at the carboxyl or amino end from a protein; these are exopeptidases. Endopeptidases or proteinases act on peptide bonds within a protein chain. As understanding of the chemical natures of the proteases advanced, it became apparent that classification of these enzymes on the basis of similarities in their active sites, the mechanisms of their catalytic action, or their tertiary structures was useful.

Regardless of origin, serine proteases feature a triad of amino acids (aspartic acid, serine, histidine) in their active site. Commonly studied examples of this type of protease include trypsin, chymotrypsin, elastase, subtilisin, thrombin, and various components of the complement cascade. The fold of the polypeptide chain(s) that make(s) up such enzymes brings the critical triad of amino acids into close proximity, even though they may be highly separated in terms of their positions along the linear (primary) sequence. The drawings in Figure 1 depict the tertiary structures of α -chymotrypsin, a

Figure 1 Representation of the tertiary structures of subtilisin and α -chymotrypsin. The computer has drawn a ribbon through the polypeptide backbone of each. Side chains for the aspartic acid, histidine, and serine residues that are essential for catalysis are shown explicitly. (Drawings prepared by Mr. E. Y. Lau using information in the Brookhaven Protein Data Bank)

serine protease from the cow, and subtilisin, a serine protease from the bacterium *Bacillus amyloliquefaciens*. Because of the separation of these two organisms in evolution, homology between their primary sequences would not be expected and none is found. Given the lack of sequence homology, the very different tertiary structures for the enzymes indicated in Figure 1 are not unexpected. However, both enzymes function in essentially the same way and have the same arrangement of the aspartate–histidine–serine triad at their active sites.

Catalysis by serine proteases involves acylation of the serine residue in the triad by transfer of the acyl group of the substrate to the enzyme (Figure 2). In a latter phase of the process, the enzyme guides a water molecule in an attack on the carbonyl group of the acylated enzyme, hydrolyzing this species and regenerating the native (active) enzyme.

In cysteine proteases, the serine of the aspartate–serine–histidine triad is replaced by a cysteine residue—in effect the nucleophilic hydroxyl group (OH) of serine is changed to the more nucleophilic sulfhydryl group (SH). Many proteases isolated from plants have proven to be cysteine proteases, including papain from the papaya, bromelain from the pineapple, and ficin from different species of *Ficus*. Cysteine proteases from mammalian tissues include the cathepsins, several related enzymes, and the calpains, which are multisubunit, calcium-dependent proteases.

Aspartic proteases utilize a constellation of aspartic acid residues at their active sites to achieve catalysis, and usually have maximal activity at low pH. The mammalian enzymes renin, pepsin, and chymosin are examples of this class of proteases, but enzymes from bacterial and fungal sources have also been extensively studied. Proteases from retroviruses are aspartate proteases and one of these, the protease from HIV-1, is presently the target of much attention.¹

Some exopeptidases include a coordinated metal atom as part of their active center. A representative of this class of metalloproteases is bovine carboxypeptidase A, which has specificity for cleaving the carboxyl terminal residue from a protein when that amino acid has an aromatic or aliphatic side chain.

Proteins are essential structural components of an organism; even the catalysts (enzymes) for a myriad of reactions that

Figure 2 Mechanism of action of serine proteases. In the first step, substrate binds to the enzyme, here represented by the symbol Enz-OH, to give a Michaelis complex. Within the complex, the hydroxyl group of the serine residue attacks the carbonyl group of the substrate to give an intermediate in which the carbonyl carbon becomes tetrahedral. Departure of the amino part of the substrate leaves the acid part covalently bound to the enzyme—the serine hydroxyl group has been acylated. The acyl enzyme undergoes attack by a water molecule and is ultimately hydrolyzed to give a complex of the acid part of the substrate with the enzyme. This dissociates to give back the native enzyme. Changes in protein conformation and dynamics probably accompany each stage of the reaction and are indicated by alterations in the dashed structures. Details of the mechanism depend on the nature of the substrate and the enzyme

take place within the organism are proteins. The activity of protein-destroying enzymes (proteases) within the organism must therefore be controlled so the organism can exist. Several strategies for achieving regulation of protease activity have evolved. (i) A protease may be produced in an inactive, incipient form called a zymogen. The zymogen is converted into active enzyme by a limited attack of another protease, and cleavage of one or two peptide bonds of the zymogen is usually sufficient to convert it into active enzyme. (ii) Proteins which inhibit specific enzymes are present in many tissues. These inhibitors bind so tightly to their target enzyme that its active site is inaccessible to substrate and water molecules. (iii) The activities of some proteases are regulated or activated by the presence of metal ions, especially calcium and magnesium. (iv) Cellular proteins are continuously turning over; the halflife for a particular protein is typically between several minutes and several days. The amount, and thus the activity, of an enzyme that is present at a given location depends on the balance between the processes leading to its formation and degradation, both of which are themselves highly regulated.

The proteases for which most information is available generally range in size from about 25 kDa to 100 kDa, although proteinases with molecular weights of 800 000 kDa are known.

Thus, except for viral proteases (ca. 14 kDa), the NMR technologies that have been developed over the past decade for the determination of the three-dimensional structures of proteins are unlikely to be productive with typical proteases, given the current state of the art.² The crystal structures of several dozen of the smaller proteases have been solved and these are the bases for virtually all information about three-dimensional structure that is available for these enzymes. However, there are inherent limits to what crystallography can tell about proteases and, as indicated by the examples below, NMR spectroscopy has contributed importantly to our understanding of many details of protease structure and function.

2 NATURE OF THE CATALYTIC TRIAD

The constancy in the appearance of the aspartate, serine, and histidine residues at the active site of serine proteases indicates that the processes of evolution have converged to a successful mechanism for catalysis, one that depends on the juxtaposition and interaction of the side chains of these amino acids. On the basis of the distances between heavy atoms and chemical intuition, it was proposed in 1969 that the structure shown in Figure 3 summarizes the interactions between these side-chains at neutral pH.³ The carboxyl group of the aspartate was presumed to be ionized, and hydrogen bonds, which involve the serine hydroxyl hydrogen interacting with nitrogen- ϵ_2 of the imidazole ring of the histidine, and the hydrogen attached to nitrogen- δ_1 of the imidazole interacting with the negatively charged aspartate side chain, were inferred. The positioning of protons in the catalytic triad of serine proteases is critical to understanding the chemical and structural reasons for the catalytic effect of these enzymes. However, X-ray diffraction studies do not reveal the positions of the hydrogen atoms in protein crystals, and the location of the hydrogens in the catalytic triad has not been without controversy.

Using frequency sweep CW NMR spectroscopy, early workers observed a very broad resonance in the range 14–18 ppm from TMS in the ^1H NMR spectra of a number of serine proteases.⁴ This signal disappeared when the solvent H_2O was replaced by D_2O and had an intensity corresponding to a single proton. It has been detected in chymotrypsinogen and trypsinogen, the zymogen precursors of chymotrypsin and trypsin, respectively, but not in proteins that do not have the catalytic triad. Assignment of this high-frequency (low-field) resonance to the proton in the hydrogen bond between histidine and aspartic acid was supported by the observation that chemical modifications of the histidine or serine residues

Figure 3 Representation of the catalytic triad of amino acids at the active sites of serine proteases, as inferred from X-ray crystallographic results

thought to prevent the formation of this hydrogen bond led to the disappearance of the signal. Unequivocal confirmation of the assignment came later from a study of α -lytic protease, a bacterial serine protease, in which nitrogen- δ_1 of the histidine imidazole was specifically labeled with nitrogen-15.⁵ In this system a doublet is observed at the high-frequency position due to spin coupling with nitrogen-15.

The high-frequency resonance of serine proteases is about 100-times broader than backbone amide N–H signals from these proteins. Studies of this signal from porcine trypsin indicate that its width, but not its position, is strongly temperature-dependent. Such observations are consistent with the notion that broadening of the peak by some kind of exchange process is present. This exchange process is presumably the interconversion of protein species with magnetically distinguishable three-dimensional structures, and appears to take place on the ms timescale.⁶

Conflicting experimental results have made the ionization behavior of the histidine residue in the catalytic triad controversial. Depending on the protein examined, with increasing pH the high-frequency ^1H NMR signal from serine proteases and their zymogens moves from its position at about 18 ppm to a position near 15 ppm. The pK_a value of the group whose titration is detected by such experiments is near 7, consistent with the expected acid–base behavior of the imidazole ring of a histidine residue in a reasonably solvent-exposed environment.⁷ Strong confirmation of normal ionization behavior for the histidine residue in the catalytic triad of serine proteases has come from ^{15}N NMR studies in which the nitrogens of the imidazole ring are labeled with nitrogen-15.⁸

Nitrogen-15 NMR spectroscopy with α -lytic protease in which one or both nitrogen atoms of the active-site histidine residue have been enriched with nitrogen-15 suggests that in solution a hydrogen bond exists between the histidine and the serine residues in the resting enzyme, as depicted in Figure 3.⁹ This conclusion is at variance with several X-ray crystallographic studies of serine proteases which have been interpreted to show that the histidine and serine residues are too far apart and improperly aligned for appreciable hydrogen bonding between them. The discrepancy between the conclusions of the NMR studies of this enzyme in solution and X-ray studies of the crystalline protein have been resolved by ^{15}N CP MAS NMR experiments with the crystalline enzyme.¹⁰ The nitrogen-15 spectrum of α -lytic protease is essentially identical in solution and in the solid state (Figure 4), indicating that the histidine–serine and aspartate–histidine hydrogen-bonding interactions are identical in the two states. It was determined that the source of the disagreement between the indications of the X-ray and NMR experiments is elevation of the histidine pK_a value to 7.9 in the solid state, so that at the pH used for the preparation of the samples examined by X-ray studies, the histidine residue is fully protonated and thus unable to participate in hydrogen bonding. Why the pK_a value of the histidine is elevated in the crystal is not clear, but this may be a consequence of the high concentration of salts present during the protein crystallization.

3 FOLDING TO ACTIVE PROTEIN

The three-dimensional structure of a protein is encoded by its amino acid sequence, although the mechanisms by which the

polypeptide becomes folded into the correct three-dimensional structure remain obscure. In Nature, serine proteases are often synthesized as precursors that have additional polypeptide attached to the C-terminal or N-terminal amino acids of the enzyme. The ‘extra’ polypeptide has a role in folding the material to the functional structure. For example, subtilisin BPN’, an extracellular serine protease from a bacillus, requires a sequence of 77 extra amino acids at its N-terminal for correct folding. This sequence is only transiently linked to the enzyme and, after folding is completed, it is autocatalytically cleaved to produce the active enzyme. It has been shown that in vitro the peptide does not have to be covalently linked to the remainder of the structure in order to exert an effect on folding.

Circular dichroism (CD) experiments demonstrate that native (active) subtilisin BPN’ is unfolded by dissolving the enzyme in 6 M guanidine hydrochloride. The majority of the secondary structural elements (helices, sheets, turns) of the protein reform when the guanidine hydrochloride is removed.¹¹ An ^1H NMR spectrum of the unfolded-then-refolded protein is shown in Figure 5. Because of local magnetic anisotropies, proteins with developed tertiary structures exhibit appreciable dispersion of the chemical shifts of the backbone peptide/amide N–H protons and, to a lesser extent, the chemical shifts of methyl protons of alanine, valine, isoleucine, and leucine side chains. Thus, the ^1H NMR spectrum of native subtilisin BPN’ [Figure 5(a)], with the amide N–H resonances spread over about 4 ppm, is typical of a protein with a well-developed tertiary structure.¹² The corresponding spectrum of the unfolded-then-refolded protein [Figure 5(b)] shows little evidence of this shift dispersion and indicates that, despite the presence of secondary structures, there is little organization of these elements into a tertiary structure.

4 PROTEASE DYNAMICS

Tosyl fluoride, and other aromatic sulfonyl fluorides, react with the serine at the active site of serine proteases to afford a protein that is inactive by virtue of the formation of a sulfonate ester with this residue (**1**). This structure is a stable analog of the acylated enzyme intermediates that are transiently present during catalysis by the enzyme (cf. Figure 2). In the case of the tosyl derivative of α -chymotrypsin, crystallographic studies show that the tosyl ring fits snugly into a depression on the surface of the protein; it is this depression or ‘tosyl pocket’ that is thought to be largely responsible for the observed specificity of chymotrypsin for the cleavage of peptide bonds adjacent to amino acid residues carrying aromatic side chains. During catalysis, the side chains of the substrates must become sufficiently immobilized that the correct orientation of the stereoelectronic features of the active site essential for catalysis is achieved, but not to such an extent that the products of the reaction cannot rapidly depart from the enzyme.

Mobility of the tosyl ring of tosylchymotrypsin has been explored by studies of the nuclear spin relaxation of carbon-13, deuterium, and tritium nuclei that have been placed in the tosyl ring. At pH 4 the data indicate that the tosyl ring moves in and out of the tosyl pocket rapidly, spending on average only about one-half of the time within the pocket. The aromatic ring of the tosyl group is considerably more mobile than would be

Figure 4 Nitrogen-15 NMR spectra of α -lytic protease in which the histidine residue has been doubly nitrogen-15 labeled. (a) Native protein in solution, (b) a frozen solution of the protein, (c) crystals of the protein. Spectra (b) and (c) were obtained with cross polarization; the signal at 255 ppm arises from nitrogen-15 at natural abundance in the amide groups of the protein backbone. The sample pH is indicated at the right of each spectrum¹⁰

expected for a group that resides exclusively in the tosyl pocket of the enzyme.¹³

The relatively high mobility of the tosyl group in this model for acylated enzymes contrasts strongly with the mobility found for acylenzyme (2). In this case the analogy of the

structure of the acylenzyme examined to the acylenzyme expected during the reaction of a specific substrate (such as one containing a phenylalanine residue) is much stronger and NMR relaxation measurements indicate that the fluorinated aromatic side chain of acylenzyme (2) is highly immobilized.¹⁴

5 INHIBITION OF PROTEASES

5.1 Protein Inhibitors of Proteases

The activity of some proteases in both plants and animals is regulated by polypeptide inhibitors that bind tightly to the active centers of enzymes. Such protein inhibitors present a

Figure 5 ^1H NMR spectrum of native subtilisin BPN' at 500 MHz (a) and of subtilisin BPN' that had been unfolded in 6M guanidine hydrochloride, then refolded by removal of this denaturing agent (b)¹²

surface that is highly complementary to that of their target enzymes, and, while they may undergo attack by the protease, products of that reaction cannot diffuse away from each other and the protease because of the strength of the interactions at the protein surfaces. For some reason leguminous plants contain extraordinarily large quantities of serine protease inhibitors. The Bowman–Burk inhibitor from soybean, a polypeptide of 71 amino acids, is an example of such an inhibitor, although it is unusual in that it has two distinct protease-binding domains, one that is specific for interaction with trypsin and another specific for chymotrypsin. The tertiary structure of the Bowman–Burk inhibitor in solution has been determined from interproton distance and dihedral angle information afforded by standard two-dimensional ^1H NMR experiments.¹⁵

The rate at which a peptide N–H proton of a protein exchanges with protons of the solvent is diagnostic of the extent to which that N–H is exposed to the solvent. Those peptide groups buried within relatively static parts of the tertiary structure of a protein, or which reside at the interface between interacting protein molecules, are protected from the solvent and exhibit reduced N–H exchange rates. The rates of exchange with solvent for the N–H

protons of the Bowman–Burk inhibitor in the absence and presence of bound chymotrypsin were determined by means of 2D ^1H NMR experiments which tracked the disappearance of N–H/ C_αH NOE cross peaks with time. The rates of N–H exchange for the residues between positions 37 and 48 of the inhibitor, with two exceptions, were dramatically slowed within the protease–inhibitor complex, indicating that these residues reside within the surface where these two components make contact with one another. Computer modeling led to a proposed structure for the chymotrypsin–inhibitor complex that is consistent with the experimental N–H exchange rate data and is similar to structures of other serine protease–inhibitor complexes that have been determined by diffraction methods.¹⁶

5.2 Natural Small Molecule Protease Inhibitors

The microorganism *Actinomycetes* elaborates a group of highly effective tripeptide-based protease inhibitors. One of the major components is leupeptin, *N*-acetyl-L-leucyl-L-leucyl-L-argininal (**3**). Tight binding of this compound to serine proteases is reasonably presumed to be the result of formation of a hemiacetal by attack of the serine residue of the active site on the carbonyl group of the C-terminal aldehyde of leupeptin. An analogous process would take place when the inhibitor binds to thiol proteases.

(3)

Attempts to demonstrate the existence of hemiacetals or hemithioacetals in these systems have produced conflicting results. ^{13}C NMR spectroscopy of leupeptin, labeled with carbon-13 at the aldehyde carbonyl, provides strong evidence that hemiacetal formation indeed occurs upon binding of leupeptin to the serine protease trypsin.¹⁷ Four carbon resonances were observed for the enriched carbon in the absence of protein: 202.1, 90.3, 76.5, and 77.0 ppm, assigned to the aldehyde form of the inhibitor, the aldehyde hydrate, and the *R*- and *S*-configurations of a cyclic carbinolamine, respectively. In the presence of trypsin, two additional signals in the spectrum at 98.8 and 97.2 ppm were observed. Based on their carbon chemical shifts and the chemical shifts of protons near the bound leupeptin that gave rise to $^1\text{H}\{^1\text{H}\}$ NOEs (detected in carbon-13 isotope filtering experiments), these signals were assigned to tetrahedral species that result from the reaction of the active site serine hydroxyl with the aldehyde group of the inhibitor. The two signals observed for the adduct correspond to the *R*- and *S*-isomers resulting from attack of the serine residue on either side of the aldehyde group of the inhibitor.

Significantly, ^{13}C CP MAS experiments with the solid leupeptin–enzyme complex showed carbon-13 signals at 98.8 and 96.5 ppm, indicating that the tetrahedral enzyme–inhibitor complexes form in the solid state and that their structures

are very similar to those detected in solution by the NMR experiments mentioned.

5.3 Synthetic Small Molecule Inhibitors

Information about the protein-bound conformation of a small molecule is useful in the design of new, better binding ligands and, thus, is an important component in the rational design of new pharmaceutical agents. Isotope editing is one of several NMR approaches useful in defining the conformations of ligands bound to proteins. These editing or filtering procedures select for observation only those signals that arise from protons attached to a hetero nucleus and their scalar-coupled or relaxation-coupled partners.¹⁸ Peptide analog (4) is an excellent inhibitor of the aspartate protease pepsin. A collection of specifically carbon-13 and nitrogen-15 labeled variants of this inhibitor has been used in isotope-edited experiments to detect NOEs between protons in different parts of the inhibitor and between protons of the inhibitor and the enzyme. These data showed that the inhibitor adopts an extended conformation when bound to pepsin.¹⁹

Another means of defining the structure of protease–small molecule complexes is through transferred NOEs. In this experiment the concentration of ligand can exceed that of its protein receptor, thus overcoming sensitivity limitations when the protein is present in inconveniently low concentrations. A requirement for this technique to be effective is that the rate of dissociation of the enzyme–small molecule complex be rapid enough that T_1 relaxation processes are at or near the fast exchange limit. The conformation of peptide (5) bound to the serine protease porcine pancreatic elastase was deduced from a set of 23 interproton distance constraints derived from two-dimensional transferred NOE experiments.²⁰

Incorporation of difluoromethyl or trifluoromethyl ketones into substrate analogs can produce excellent inhibitors of serine or thiol proteases. The carbonyl group of these materials is rendered highly electrophilic by the electron-withdrawing effects of the adjacent fluorine atoms and is a likely target for attack by the reactive serine or cysteine at the active sites of

these enzymes. An example is peptide analog (6) which is an inhibitor of chymotrypsin.²¹

Fluorine chemical shifts in such structures are sensitive to hydration or hemiketal formation and enzyme binding. For compound (6), ¹⁹F, ¹³C, and ¹H NMR observations led to the conclusion that the keto group of the inhibitor is present in the enzyme environment as an ionized hemiketal, such that the enzyme is able to stabilize a tetrahedral oxyanion form of the inhibitor that is presumably analogous to the tetrahedral intermediates that form during catalysis (Figure 3).

Carboxypeptidase, a metalloexopeptidase, is inhibited by 2-benzyl-4-oxo-5,5,5-trifluoropentanoic acid (7). Comparison with the structure of a peptide substrate of the enzyme (8) indicates that the electrophilic keto group in (7) is well positioned for undergoing attack by a nucleophilic group at the active site. However, X-ray crystallography has shown that, at least in the crystalline state, it is the ketone hydrate that is bound to the enzyme.

Fluorine NMR studies of the trifluoromethyl ketone show a single sharp resonance which has been assigned to the hydrate, a conclusion additionally supported by carbon-13 data. In the presence of carboxypeptidase two broad ¹⁹F NMR signals were observed and assigned to the complex formed by the protein-bound trifluoromethyl ketone hydrate in the L-configuration and the complex in which hydrate is the D-enantiomer. Competition studies showed that 2-benzylsuccinate, a good competitive inhibitor of the enzyme, preferentially displaced the L-isomer.²²

6 NEW PROTEASES

Conversion of the essential serine residue at the active center of serine proteases by chemical means to cysteine or selenocysteine has been achieved. These new enzymes remain catalytically active but a change of the OH group at the active site to SH or SeH alters the reactivity, specificity, or stability of the enzyme. Selenosubtilisin, produced by ‘mutating’ the active site serine residue of the protease subtilisin Carlsberg to selenocysteine, has been examined by ⁷⁷Se NMR.²³ Selenium chemical shifts span a 3400 ppm range and are extremely sensitive to the oxidation state. Protein crystallography is not useful in characterizing the oxidation state of selenium, and this system provides another example of how NMR observations can provide detailed information about proteases that is complementary to the results of diffraction experiments.

The enzyme was found by NMR to exist in selenolate, selenyl sulfide, and selenic acid forms. The first two of these are catalytically active. Like the serine proteases, these

selenium-containing enzymes exhibit highly deshielded proton resonances at roughly 18 ppm from TMS. This signal can be assigned with some confidence to the proton attached to nitrogen- δ_1 of the histidine residue at the active site. In contrast to native subtilisin, the seleninate and selenoate analogs show a second N-H resonance at 14–15 ppm which has been assigned to a proton bonded to nitrogen- ϵ_2 of this histidine. This proton is evidently positioned to engage in hydrogen bonding with the adjacent seleninate or selenolate group. Involvement in a strong hydrogen bond would be consistent with the resistance of this N-H hydrogen to exchange with solvent, as indicated by the ^1H NMR data. Studies of pH dependence indicated that the pK_a value of the active site histidine must be at least 3 pH units higher than the pK_a value of the corresponding histidine in the native, serine-containing enzyme.

Protein engineering technologies now make available an infinite variety of new proteases that differ from their native progenitors by one or more amino acids. It will be interesting to see what NMR observations can reveal about the structural and functional consequences of these mutations.

7 PROTEASES IN ORGANIC SOLVENTS

There is burgeoning interest in the use of proteases as catalysts in organic solvents or other nonstandard media for the cleavage of bonds, or for the formation of bonds by forcing the enzymatic hydrolysis reaction to 'run backwards'.²⁴ Solid state ^{15}N NMR studies of histidine-labeled α -lytic protease crystals suspended in a variety of organic solvents suggest that the structural integrity of the active center of this protease remains unperturbed in several organic solvents, including acetone and octane, but appears to be lost when the enzyme is exposed to dimethyl sulfoxide. Alternation of the catalytic activity of this enzyme by organic solvents appears not to be always due to a loss of the critical orientations of the residues of the catalytic triad in these media but the result of other considerations.²⁵

8 SUMMARY

Most proteases are too large to be realistic candidates for three-dimensional structure determination by NMR methods. However, NMR experiments have been used to provide important details of protease structure and function, and have been important in demonstrating the extent to which conclusions about protease structure and function based on crystallographic (solid state) results are applicable to the corresponding proteins in solution. NMR results can uniquely provide information about structural dynamics and the binding of large and small molecules to proteases that is not obtainable by crystallography.

1 INTRODUCTION

Although the introduction and development of multidimensional ^1H NMR techniques over the last 10 years has revolutionized the structural elucidation of proteins with $M_r \leq 35$ kDa, the majority of enzymes fall outside this molecular weight range. Thus for larger enzymes, the complete structure cannot currently be determined by NMR. But one of the distinguishing features of NMR spectroscopy as a technique for structural biology is its ability to provide crucial structural information about a specific part or region of a molecule. This sets NMR apart from other structural techniques such as X-ray crystallography, in which in general the whole structure must be completely solved before a selected region can be investigated. This ability to focus on structural regions of interest is no more important than in the field of protein function, where the relationship between structure and function is intimately connected at the enzyme active site. The use of heteronuclear MR, in particular nuclei such as ^{13}C , ^{15}N , ^{19}F , and ^{31}P , has been important in providing the means to focus on enzyme active sites for proteins whose $M_r = 25$ –100 kDa.

In this article we will consider the ways in which such heteronuclear NMR approaches may be applied to the study of enzyme–substrate interactions, and specifically consider the approach of time-resolved solid state NMR spectroscopy, which was introduced recently by our laboratory.

2 WHICH TYPES OF ENZYMES CAN BE STUDIED BY NMR?

Not all enzymes are amenable to study by NMR spectroscopy. The limitations arise because of a number of factors, the two most important being: molecular weight, M_r , and also the k_{cat} of the enzyme. We will consider the effects of these limitations in sections 3 and 4. The types of functional information that can be obtained on enzymes may be summarized as follows:

1. The flux of isotopically labeled substrates to products through an enzyme-catalyzed pathway may be obtained by solution state NMR. This can lead to the identification of enzyme-free intermediates.
2. The structure of an isotopically labeled inhibitor bound to an enzyme may be determined by solution state ($M_r \leq 50$ kDa) or solid state ($M_r \leq 150$ kDa) NMR. This can be used in conjunction with protein structural methods by NMR or X-ray crystallography, for the identification of functional residues in the enzyme active site and a possible rôle in catalysis.
3. The structure of an enzyme–substrate or enzyme–intermediate complex of a multisubstrate enzyme with an insufficient number of substrates for the reaction to proceed can be carried out by solution state or solid state NMR.
4. The structure of an enzyme–substrate or enzyme–intermediate complex of a freely reversible enzyme can be determined by solution state or solid state NMR by balancing the concentrations of substrate and product, and allowing maximum accumulation of intermediate (depending on k_{cat} , K_M , and exchange rates).
5. The structure of an enzyme–substrate or enzyme–intermediate complex can be determined at low temperature by cryoenzymological solution state NMR and solid state NMR.

We will discuss these methods in more detail in Section 4.

In the foregoing list, the word ‘structure’ is used frequently, and it is important to realize the limits of the structural information that can be obtained. Clearly the molecular weight will affect the detail of the information obtainable, or put more formally, above $M_r = 35$ kDa, there is an inverse relationship between the number of distance restraints and molecular weight. The same sorts of considerations that apply to high-resolution ^1H NMR of proteins also, of course, apply to enzymes. Therefore alternative strategies have to be adopted to obtain structural information. The use of isotopic labels introduced at specific locations in the enzyme substrate or inhibitor molecule can be used for heteronuclear MR studies. But the detection of the resonance from such an isotope provides, in the first instance, only a chemical shift. This can be highly diagnostic: for example, if the enzyme catalyzes the cleavage of an amide bond via a tetrahedral sp^3 carbon, then the ^{13}C resonance would shift from around 200 ppm to around 100 ppm. But chemical shifts, a structure do not make! By analogy with the chemical shifts of model compounds, together with pH titration behavior, relaxation data, and J coupling data (e.g. for heteronuclei the spectrum can be obtained with and without ^1H decoupling), a structure can be deduced. However, the information that is most useful is distance or torsion angle restraints of some kind, from NOEs, transferred NOEs, paramagnetic relaxation enhancements, or dipolar couplings. Only with this information coupled with the other data, can the structure of a substrate, inhibitor, or intermediate be determined with any certainty.

The relationship of that ligand to the rest of the biomolecule poses a different type of problem, and yet again distance or torsion angle restraints are the data required to resolve it. Sometimes distance or torsion angle restraints can be used in conjunction with a low-resolution X-ray crystal structure, or an X-ray structure of the protein in the absence of ligand, in docking experiments. Above all it is the quality rather than the quantity of restraints that helps to define good structures for

larger enzyme-substrate or enzyme-intermediate complexes. This is in contrast to smaller protein structures, in which the quantity of relatively poor-quality distance restraints can generate remarkably accurate and in some cases precise structures.

3 LINEWIDTHS IN ENZYME COMPLEXES

In any NMR investigation of an enzyme complex, whether this involves heteronuclear studies of isotopically enriched substrates or intermediates, or homonuclear studies of the protein itself, the single most important factor crucial to successful detection of the resonance of interest is its linewidth. The linewidth of an NMR resonance is given by:

$$\Delta\nu_{\frac{1}{2}} = \frac{1}{\pi T_2^*} \quad (1)$$

where $\Delta\nu_{\frac{1}{2}}$ is the linewidth at halfheight, and T_2^* is the apparent transverse relaxation time. Linewidths in enzyme complexes are determined essentially by two factors: (i) the overall rotational correlation time, τ_c , of the macromolecule, or (ii) chemical exchange. The rotational correlation time for globular proteins may be calculated using the Stokes-Einstein equation:

$$\tau_c = \frac{4}{3} \pi r^3 \frac{\eta}{k_B T} \quad (2)$$

where r is the molecular radius, η is the viscosity of the medium, k_B is Boltzmann's constant, and T is the temperature in kelvin. Assuming $M_r \propto r$,

$$\tau_c \approx M_r \times C \quad (3)$$

where C is typically 1.3×10^{-12} (calculated from T_1 values for backbone α -carbons at field strengths ≤ 2.4 T).¹ Note that this latter relation is *very* approximate.

Such an estimate of rotational correlation time is based on the assumption that the overall tumbling rate dominates the relaxation for nuclei in this molecule, even if it is a small molecule complexed with a large one such as an enzyme-substrate or enzyme-intermediate complex. There are exceptions to this, in which the local librational motion is greater than the tumbling. In these cases, mobile domains are detectable even in very large proteins.

4 DIRECT OBSERVATION OF ENZYME-SUBSTRATE/INTERMEDIATE COMPLEXES

The quest for an understanding of the molecular details of enzymatic catalysis has been a major motivation for much biochemical and biophysical research during the last decade. A crucial part of this endeavor has been the structural investigation of intermediates, which has played an important rôle in the elucidation of enzymatic reaction mechanisms. An enzymatic reaction mechanism can be said to be understood when (i) the enzyme-bound intermediate(s) can be detected and its structure determined; (ii) the kinetic competence of the enzyme has been demonstrated (i.e. the rate of formation

and degradation are consistent with the forward and reverse reaction rates);² and (iii) the internal microscopic rate data are consistent with a reaction pathway in which all thermodynamic and kinetic states have been described. The use of ^{31}P , ^{13}C , and ^{15}N NMR in solution is a well-established technique for the study of enzymatic reaction mechanisms.^{1,3-5}

The elucidation of the structure of an enzyme-substrate complex at various points along the reaction coordinate is one of the most sought-after goals of enzyme chemistry. Currently there are two approaches to stabilizing enzyme-intermediate complexes so that they can be examined by NMR: low-temperature solution state cryoenzymological NMR, and the recently introduced method of time-resolved solid state NMR spectroscopy.

4.1 Cryoenzymology

There are a considerable number of enzymatic reactions for which the catalytic rate is too fast for significant accumulation of intermediates during the reaction. In this case, the idea of lowering the temperature to slow the rate is straightforward. The kind of reduction in reaction rates can be quite significant.⁶ To prevent freezing of an aqueous solution of an enzyme and substrate below 0°C, cryosolvents are employed. In general the cryosolvent needs to be inert, and commonly 40–50% dimethyl sulfoxide (DMSO)-water is used. Unfortunately, the viscosity of this cryosolvent also increases at lower temperatures, resulting in increases in linewidth. For example there is a fourfold increase in linewidth in going from 0 to –20°C in 40% DMSO-water. The use of a cryosolvent and low temperatures requires careful kinetic characterization of the enzymatic reaction under the new conditions, to ensure that the reaction pathway has not been altered. Furthermore, the current molecular weight limit is around 50 kDa.⁶ This method has been applied to a number of enzymes, and application of solution state NMR spectroscopy to the study of enzyme-intermediate complexes at subzero temperatures can provide valuable data (chemical shift, relaxation times, J coupling, and NOEs).^{7,8}

4.2 Time-Resolved Solid State NMR Spectroscopy

One way to circumvent some of the disadvantages of solution state cryoenzymology is to use the recently developed method of time-resolved solid state NMR spectroscopy.⁹⁻¹¹ In the past, study on intermediate species has depended upon their isolation from the reaction mixture and therefore limited to relatively stable, long-lived species. With the advent of spectroscopic techniques, it has become possible to investigate these intermediate species *in situ* during the reaction. However, the techniques that have gained the widest application have been those which furnish the least structural information, namely UV-visible spectroscopy, IR spectroscopy, Raman spectroscopy, and ESR spectroscopy. The two techniques that generate the most structural information, X-ray crystallography and NMR spectroscopy, also are among the slowest and most insensitive methods for the data collection. In the case of X-ray crystallography, the technique is wholly dependent upon obtaining suitable crystals, which is not a trivial undertaking. To date the best time-resolution achieved

with cryoenzymological methods¹² has been of the order of 0.5 h, although with the recent developments in Laue diffraction methods^{13–16} time-resolved kinetic studies of enzymatic reactions have been reported¹⁷ with time-resolutions of 1–3 s, and in theory it should be possible to carry out kinetics at time-resolutions in the millisecond regime.¹⁸ However, there are intrinsic limitations to the time-resolved Laue diffraction methods, since diffusion of the substrate results in a kinetically inhomogeneous population of enzyme-bound intermediate states, and transient lattice disorder during substrate entry results in diffuse electron densities just at the time when the reaction takes place. These latter problems have been mitigated to some extent by employing caged substrate molecules, where a photo-releasable version of the substrate is cocrystallized with the enzyme, and photo-release of the substrate synchronized with X-ray irradiation.^{19,20} Even with this approach, the Laue method only provides somewhat diffuse electron density maps for the substrate or intermediate, to which it is difficult to fit a precise structure. This is not too surprising, since during catalysis it is to be expected that the enzyme-bound substrate or intermediate are dynamic and undergoing significant molecular motion.

Although NMR spectroscopy has been used to study rapid reactions in solution, in particular by continuous-flow and stopped-flow methods,^{21,22} the time-resolution is at very best about 20 ms and in practice of the order of 200 ms to >10 s. In time-resolved solid state NMR spectroscopy, the time-resolution achievable is of the order of about 2 ms. Other pre-steady-state techniques use quenching reagents to halt the reaction and then study the reaction mixture at leisure by various analytical techniques such as chromatography. The chemical quench-flow technique²³ has been used to identify one enzyme-intermediate for 5-enolpyruvylshikimate 3-phosphate (EPSP) synthase (EC 2.5.1.19) with subsequent analysis by solution state NMR spectroscopy.²⁴ EPSP synthase is a monomer with a molecular weight of 46 kDa and a key enzyme in the aromatic amino acid biosynthetic pathway that catalyzes the formation of EPSP [(4) Scheme 1] from shikimate 3-phosphate [S3P, (1)] and phosphoenolpyruvate [PEP, (2)] (see Scheme 1). The vulnerability of relatively unstable enzyme–intermediate complexes to a chemical quench is a major concern with this technique. It is important to realize that an intermediate that has been isolated could result from rearrangement or breakdown of another intermediate, which itself might be on the reaction pathway.²⁵ It would therefore seem preferable to detect the intermediate directly *whilst still bound to the enzyme*, and a less disruptive method of quenching is required in order to do this.

The idea of thermal quenching first came to light in the 1960s. The essential requirement of any rapid quench process is that it is fast compared with the reaction being studied. A technique was devised^{26,27} to freeze rapidly a reaction solution at a rate on the order of 10^5 K s^{-1} and then to examine the frozen sample by ESR spectroscopy. The impetus behind the need for low temperatures was not only to quench the reaction and allow the use of slow and repetitive scanning techniques, but also because many paramagnetic centers can only be observed at low temperature.

Studies^{28–30} of the effects of freezing on proteins have determined that the destructive aspect of the process is the formation of hexagonal ice. So long as the freezing process

Scheme 1 Reaction catalysed by EPSP synthase

is fast ($\geq 10^5 \text{ K s}^{-1}$) and/or cryoprotectants (e.g. glycerol) are used, the majority of enzyme activity can be retained throughout the freezing process. Furthermore the frozen water is probably largely amorphous,³¹ with the protein itself acting in a similar manner to a cryoprotectant³¹ thereby reducing the formation of hexagonal ice that is detrimental to the protein. We have also found that the effects of the rapid freezing technique^{9,32} are consistent with minimal possible damage to the protein.

In contrast to cryoenzymological solution state NMR, with solid state NMR spectroscopy³³ line broadening due to chemical shift anisotropy and dipolar coupling can be reduced by CP MAS, so that there is theoretically no known molecular weight limit, since the rotational correlation time governs only the nuclear relaxation properties under MAS. The key therefore is the use of solid state NMR methods in conjunction with rapid freeze–quench methods, so that short-lived enzyme intermediates can be trapped. For this method, while knowledge of the pre-steady-state kinetics for the enzyme can be helpful, it is not a requirement, since the method can be used without prior knowledge in much the same way that other physical methods used to measure pre-steady-state kinetics start with initial guesses at the reaction time. Indeed time-resolved solid state NMR seems to be emerging as an alternative strategy for carrying out pre-steady-state kinetic analyses, which is superior to monitoring substrate consumption or product appearance by chromatographic techniques, since with these approaches there is always uncertainty as to the precise origin of the species being analyzed. Time-resolved solid state NMR spectroscopy essentially provides ‘snapshots’ of all the species, free and enzyme-bound, present at a particular time into the reaction. Furthermore, without the need for lengthy kinetic studies in cryosolvents, the method may be simpler and easier to use than cryoenzymological solution state NMR. The disadvantages are that considerable quantities of protein are required (on the order of 100 mg per time point), although with modern

Figure 1 The apparatus used for rapid freeze–quench of intermediates in time-resolved solid state NMR

overexpression systems, this needs to be a limiting factor, and also a reaction with a k_{cat} of 10^{-5} s and a large activation enthalpy (e.g. -25 kJ mol^{-1}) will not be quenched even at -75°C . The latter limitation is not too severe, given the number of enzymatic reactions that do not fall into this category.

The rapid freeze–quench method involves rapidly mixing enzyme and substrate together and freezing by spraying the mixture directly into a secondary cryogen such as liquid propane cooled to $\sim 85 \text{ K}$ (see Figure 1).

Figure 2 shows time-resolved solid state ^{13}C CP MAS NMR spectra of EPSP synthase mixed with $[^{13}\text{C}]$ substrate under pre-steady-state conditions with the time elapsed from the start of the reaction indicated. The intermediate ($\text{E} \cdot \text{I}$) is clearly visible at 104 ppm and its buildup demonstrated as the reaction proceeds. On allowing the pre-steady-state reaction to proceed for a few minutes, the turnover of intermediate ($\text{E} \cdot \text{I}$) to product ($\text{E} \cdot \text{EPSP}$) is evident. In addition to the resonance due to the $\text{E} \cdot \text{I}$ complex, the resonance due to the free product (EPSP) builds up at 155 ppm, and the free PEP decays at 151 ppm.

Although the $\text{E} \cdot \text{I}$ signal could be followed by direct integration, the enzyme-free $[^{13}\text{C}]\text{PEP}$ and $[^{13}\text{C}]\text{EPSP}$ could not. These two signals were therefore resolved by deconvoluting the overlapped resonances by peak fitting with fixed linewidths. The linewidths used were obtained from ^{13}C spectra of the substrates/products (Figure 2), and from averages of linewidths obtained from unfixed peak fits. The peak fitting routine determined the peak height and integral (assuming Lorentzian lineshape) for each time point, and the deconvoluted spectra obtained are shown in Figure 3. The chemical shifts obtained from the fits are $\delta_{\text{C}}([^{12}\text{-}^{13}\text{C}]\text{PEP}) = 150.1 \text{ ppm}$ and $\delta_{\text{C}}([^{12}\text{-}^{13}\text{C}]\text{EPSP}) = 153.4 \text{ ppm}$. The peak intensities of all the individual species were normalized to the protein carbonyl resonance at $\delta_{\text{C}} = 174.2 \text{ ppm}$. This was

Figure 2 Carbon-13 TOSS CP MAS spectra of EPSP synthase (4 mM)/S3P (40 mM)/ $[2\text{-}^{13}\text{C}]\text{PEP}$ (40 mM) frozen mixtures, rapidly quenched in the forward direction at 20, 30, 40, 50, 100 ms and slow frozen after several minutes (10^5 ms). The spectra were acquired on the 7 mm probe in 12 000 scans using a $4 \mu\text{s}$ pulse width, 0.5 s contact time, and 2 s relaxation delay, and processed with 100 Hz line broadening and zero filling up to 8K data points. The spectra are shown with absolute intensity and normalized to the protein resonance at $\delta_{\text{C}} = 174.2 \text{ ppm}$. performed to account for experimental variations in the sample volume due to different mixing programs and delay lines.

As noted for the chemical quench analysis,²³ the availability of software for the simulation of enzyme kinetics has revolutionized the fitting of pre-steady-state kinetic data since the entire data can be fitted to one mechanism and set of microscopic rate constants. The first stage of fitting the NMR integral data was to convert the arbitrary integral values into useable concentrations. Quantifiability of ^{13}C CP MAS NMR spectra has been addressed previously³⁴ and it is known that signal intensities are dependent on the kinetics of magnetization transfer during CP. At sufficiently long contact times spectra are approximately quantitative, even without normalization. In the case of EPSP synthase, the integral–concentration relationship can be determined from the direct NMR spectra of the free substrates and products, or an equilibrated enzyme solution by using the overall $K_{\text{eq}} = 180$. Of course there is a caveat³⁵ with this approach, which is that a good fit of experimental data to a proposed model using a kinetic simulation program, even over a wide range of experimental conditions, does not prove a mechanism to be correct.

In the forward direction, the integrals were standardized against the EPSP signal at equilibrium (Figure 2, 10^5 ms) and alone in frozen solution. A kinetic simulation

Figure 3 Peak fitting of the forward reaction of EPSP synthase for (a) enzyme-free $[2-^{13}\text{C}]$ PEP and $[8-^{13}\text{C}]$ EPSP and (b) the enzyme-bound intermediate ($\text{E} \cdot \text{I}$). The fits were performed within FELIX using the simulated annealing algorithm. Constrained linewidths were used and these were estimated from averages of initial, unconstrained fits. Constrained peak positions were used for (a) in order to deconvolute the resonances successfully. Reprinted with permission from Appleyard et al.¹¹ Copyright 1994 American Chemical Society

was performed using the equilibrium ordered mechanism (Scheme 2) and the starting concentrations of 4 mM $\text{E} \cdot \text{S3P}$, 36 mM S3P, and 40 mM $[2-^{13}\text{C}]$ PEP. The previously determined kinetic rate constants²³ were used as a starting set, but the kinetic parameters could not be fitted to these converted concentrations either by manual interaction or with a computer fitting program. There was a good correlation between each set of experimental data and the corresponding simulation data, and the problem was the relative ratios between reaction species. By calculating early (10 ms) and final equilibrium concentrations for each species using a simulation, the integrals for each species were independently standardized. The resulting concentrations were then plotted along with the simulated data (Figure 4). A similar analysis was performed on the reaction species in the reverse direction.¹¹

Figure 4 Plot of the experimental (points) and simulated (lines) concentrations of enzyme-free $[2-^{13}\text{C}]$ PEP, enzyme-free $[8-^{13}\text{C}]$ EPSP, and enzyme-bound intermediate ($\text{E} \cdot \text{I}$) against the reaction time in the forward direction. Simulations performed using sequential ordered mechanism, full set of rate constants²⁴ and starting concentrations of 4 mM $\text{E} \cdot \text{S3P}$, 36 mM S3P, and 40 mM $[2-^{13}\text{C}]$ PEP. Laue X-ray diffraction and time-resolved solid state NMR obviously achieve similar goals, and each technique has its drawbacks. In the Laue method, large B factors are observed for mobile atoms, which lead to a blurred image of critical areas, e.g. substrates and active-site residues. It is also impossible to differentiate between the superimposed kinetic states in an electron density map. In the NMR method, chemical shift overlap of reaction species can be a problem but a change in hybridization in a reaction results in discrete chemical shift changes, allowing differentiation between kinetic states. The dipolar interaction can also be used, although it is limited because only pairwise internuclear distances can be measured at any one time. Recently, a number of solid state NMR pulse sequences have been developed^{36–40} that can selectively reintroduce the dipolar interaction and allow the determination of very accurate distances.^{41–43} The prospect of detailed internuclear distance measurements puts solid state NMR on the verge of a transformation similar to that which solution state NMR underwent with the introduction of two-dimensional techniques. Thus the Laue and NMR techniques complement rather than compete against one another. The strength of the former lies in generating a global picture, whereas the latter can focus on the enzyme active site and generate specific distance information.

Time-resolved solid state NMR spectroscopy provides a major technological advance in the study of enzymatic reaction mechanisms. One important consideration in any attempt to detect transient intermediates in addition to their lifetimes, is their pre-steady-state concentrations. This is dependent upon the kinetics and thermodynamic stability of intermediates of

Scheme 2 Kinetic mechanism of EPSP synthase

each individual enzyme. Some enzymes, like EPSP synthase, have unusually stable intermediates. However, following the notions of Albery and Knowles,⁴⁴ we would expect that the majority of enzymes are evolving toward 'perfection', and stabilize highly unstable intermediates. For example, with triose phosphate isomerase (TIM) at equilibrium, the concentration of the postulated intermediate bound to the enzyme is approximately 5% of the total substrate concentration (with enzyme in excess). While the intermediate of TIM is probably beyond the limits of detection by time-resolved solid state NMR spectroscopy, a labeled intermediate bound to enzyme (at concentrations of 1–4 mM) greater than or equal to 10% of the protein concentration (with substrate in excess), can be detected using careful difference spectroscopy. While that excludes the 'perfect' enzymes, there remain a large number of enzymes for which this approach will still be very powerful. Furthermore, when coupled with the elegant solid state NMR distance-measurement methods that have been introduced recently (see **REDOR and TEDOR; Rotational Resonance in Biology**) time-resolved solid state NMR could be used to 'map out' molecular conformations of intermediates and enzyme-active-site–intermediate distances as an enzymatic reaction proceeds. This would provide the crucial missing structural details which Laue X-ray diffraction and allied techniques cannot provide, and enable the complete definition of the molecular events of enzyme catalysis.

1 INTRODUCTION

The importance of diet in both the preservation of health and treatment of disease is increasingly recognized. The major causes of morbidity and mortality in the Western world include cancer, coronary heart disease, diabetes mellitus, and obesity. Nutrition appears to have a major role both in their treatment and prevention.^{1,2} There is therefore a growing need for the application of current scientific techniques to nutritional studies, to delineate the response of human metabolism to dietary alterations. The development and use of spectroscopy for nutritional studies is a major recent advance.

The last decade has seen increasing interest in the use of both in vivo and in vitro NMR spectroscopy for investigation of human and animal metabolism. Researchers are taking advantage of the nondestructive and noninvasive nature of the technique. These characteristics are particularly important for widespread, population-based studies of human nutrition, which often require serial examinations.

The initial applications of NMR to dietary studies were principally concerned with development of the NMR methodology, rather than focusing on specific nutritional and biochemical problems.^{3,4} However, even at this early stage the potential of NMR spectroscopy when applied to lipid and glycogen metabolism could be envisaged. In this article we will review the recent use of in vivo and in vitro NMR spectroscopy for the investigation of the metabolic effects of diet.

2 USEFUL NUCLEI FOR DIETARY STUDIES

Carbon-13, ²H, ¹H and ³¹P NMR techniques have all been applied to study the effects of dietary manipulation in animals and humans.³⁻⁹ Limited information can be obtained with in vivo ³¹P and ¹H NMR spectroscopy as applied to nutrition. Phosphorus-31 NMR detects only phosphate-containing compounds; ¹H NMR suffers from a small chemical shift range, resulting in severe signal overlap and signals near the water resonance which cannot be readily detected. This has meant that ¹H and ³¹P NMR techniques have principally been applied to dietary studies in vitro.¹⁰⁻¹² However, ²H and ¹³C

NMR methods have been used in elegant in vivo metabolic studies.

The deuterium nucleus is quadrupolar ($I = 1$). It has both a low gyromagnetic ratio and natural abundance (0.015%), which leads to a very low sensitivity relative to proton spectroscopy (1.45×10^{-6}). These unfavourable properties are offset by its short relaxation times and high body content (12 mM), allowing its detection by natural abundance in vivo NMR spectroscopy. Furthermore, the tissue content can be readily increased by the use of deuterated water (D₂O), a fact that Brereton et al.⁵ have utilized to great effect in lipid turnover studies.

Carbon-13 NMR spectroscopy in vivo has also been successfully applied in dietary studies.^{3,4,8,9} Compared with ¹H NMR, ¹³C NMR spectroscopy is very insensitive due to the low gyromagnetic ratio and low natural abundance (1.1%) of the ¹³C nucleus. Its relative sensitivity is further reduced by the ¹H-¹³C coupling which splits the ¹³C signal, effectively reducing intensity. These problems are partially offset by the short relaxation times of most ¹³C resonances, the use of decoupling techniques, and the high tissue content of important dietary-related, ¹³C-containing compounds, including lipids and glycogen. Moreover, the very fact that ¹³C has 1.1% natural abundance has been exploited by using ¹³C-enriched metabolites in turnover studies, similar to classical ¹⁴C tracer studies.

3 IN VIVO NMR SPECTROSCOPY

3.1 Lipid Metabolism

3.1.1 Carbon-13 NMR Spectroscopy

High-resolution ¹³C NMR spectroscopy has found widespread use in the study of lipids in vitro.^{13,14} In particular, the clear distinction of multiple different fatty acid groups allows this technique to be used, often quantitatively, in studies of dietary oils.¹⁵⁻¹⁸ This degree of resolution cannot be achieved in vivo, which limits the utility of this technique in noninvasive human research. However, major lipid groups can be distinguished and, within these constraints, important clinical and biochemical work has been carried out using proton-coupled ¹³C and proton-decoupled ¹³C{¹H} NMR spectroscopy.

Canioni et al.³ first showed that in vivo ¹³C{¹H} NMR spectroscopy could detect differences in the lipid composition of adipose tissue and liver in rats fed a diet high in polyunsaturated fatty acids. Further work by Sillerud et al.¹⁹ examined ¹³C{¹H} NMR of triacylglycerols in rat adipocytes in vivo, advancing our knowledge particularly of signal assignment in biological systems. Moonen et al.⁴ developed in vivo ¹³C{¹H} NMR to characterize adipose tissue in human subjects. They confirmed that linoleic acid (C_{18:2n-6}), usually the principal polyunsaturated fatty acid present in human adipose tissue, dominated the polyunsaturated fatty acid carbon signal observed in vivo, allowing estimation of this stored essential fatty acid. A typical ¹³C NMR spectrum of human adipose tissue is shown in Figure 1.

Barnard et al.⁹ demonstrated the capability of in vivo ¹³C{¹H} NMR spectroscopy to monitor the effect of diet on

Figure 1 Natural abundance in vivo $^{13}\text{C}\{^1\text{H}\}$ NMR spectrum of human adipose tissue, dominated by signals from triacylglycerols. Peak assignment (referenced to $-\text{CH}_3$): 1, $\text{C}=\text{O}$ (171.79 ppm); 2, $-\text{CH}=\text{CH}-$ (monounsaturated) and $-\text{CH}=\text{CHCH}_2\text{CH}=\text{CH}-$ (polyunsaturated) (129.83 ppm); 3, $-\text{CH}=\text{CHCH}_2\text{CH}=\text{CH}-$ (polyunsaturated) (128.13 ppm); 4, C-2 glycerol (69.21 ppm); 5, C-1, C-3 glycerol (62.05 ppm); 6, $-\text{CH}_2\text{CH}_2\text{CO}_2\text{R}$ (33.93 ppm); 7, $-\text{CH}_2\text{CH}_2\text{CH}_3$ (32.14 ppm); 8, $-(\text{CH}_2)_n-$ (29.69 ppm); 9, $-\text{CH}_2\text{CH}=\text{CH}-$ (27.39 ppm); 10, $-\text{CH}_2\text{CH}_2\text{CO}_2\text{R}$ (25.04 ppm); 11, $-\text{CH}_2\text{CH}_2\text{CH}_3$ (22.94 ppm); 12, $-\text{CH}_2\text{CH}_3$ (14.1 ppm)

adipose tissue in rats. In animals fed fats with different fatty acid patterns (butter/lard, olive oil, sunflower oil, fish oil), clear differences were found in the in vivo spectra, consistent with a significant effect of dietary fatty acid intake on the tissue fatty acid profile. Progressively increasing the total unsaturated and polyunsaturated fatty acid content in the diet was reflected in the adipose tissue composition (Figure 2), and results were correlated with in vitro spectroscopy and gas chromatography analyses. In humans, the turnover of fatty acids in adipose tissue is slow ($T_{1/2} = 600$ d). The fatty acid profile of human subcutaneous fat therefore provides an index of the habitual dietary fatty acid intake over the previous 2–3 years.²⁰ This is of importance in long-term epidemiological surveys, but has previously been limited by the need for repeat tissue biopsies for fatty acid estimation. The application of in vivo ^{13}C NMR spectroscopy to the noninvasive analysis of adipose tissue composition is therefore of particular value for human nutritional studies.

Beckmann et al.⁸ have used in vivo ^{13}C NMR to show a significant change in human adipose tissue fatty acid composition following a fat-reduced diet, with a correlation between diet and tissue monounsaturated fatty acids. No difference was found in the degree of polyunsaturation, and this may reflect the limited 6 month period of dietary change. Bryant et al.²¹ chose to study vegan subjects as a defined population, with an established long-term diet, high in polyunsaturated fatty acids. A significantly increased adipose tissue total unsaturated and mono- and polyunsaturated fatty acid carbon content was shown in the ^{13}C spectra from the vegan group compared with omnivore controls (Figure 3). In addition, this was associated with a significant reduction in plasma concentrations of total cholesterol (4.55 ± 1.30 versus

Figure 2 Olefinic region of natural abundance in vivo $^{13}\text{C}\{^1\text{H}\}$ NMR spectra of epididymal fat pad in rats fed fats high in different fatty acids. Unsaturated fatty acid carbon resonances appear in this region: monounsaturated ($-\text{CH}=\text{CH}-$) and polyunsaturated ($-\text{CH}=\text{CHCH}_2\text{CH}=\text{CH}-$) at 129.8 ppm; polyunsaturated ($-\text{CH}=\text{CH}-\text{CH}_2\text{CH}=\text{CH}-$) at 128.2 ppm. (a) Butter/lard diet—saturated fatty acids; (b) olive oil diet—monounsaturated fatty acids [oleic acid ($\text{C}_{18:1n-9}$)]; (c) sunflower oil—polyunsaturated fatty acids [linoleic acid ($\text{C}_{18:2n-6}$)]; (d) fish oil—($n-3$) polyunsaturated fatty acids [($\text{C}_{20:5n-3}$) and ($\text{C}_{22:6n-3}$)]. In these rats, adipose tissue lipid composition measured by NMR correlates to dietary content. Increasing dietary unsaturated and polyunsaturated fatty acid content produces similar changes in the adipose tissue, shown by an increasing total signal from $\text{C}=\text{C}$ carbons and an increasing signal from polyunsaturated carbons at 128.2 ppm. Further, there appears to be a novel peak (*) at 132 ppm from unsaturated carbons at the $n-3$ position ($-\text{CH}=\text{CHCH}_2\text{CH}_3$), a double bond particularly found in the $n-3$ fatty acids of fish oil

$5.39 \pm 1.42 \text{ mmol l}^{-1}$, $p < 0.05$) and low-density lipoprotein (LDL) cholesterol (2.72 ± 1.06 versus $3.37 \pm 1.34 \text{ mmol l}^{-1}$, $p < 0.05$) in the vegan subjects. The complex interactions between lipids in plasma and the body tissues are not fully defined, but are likely to be the subject of future NMR-based, dynamic studies of nutrition and lipid metabolism.

The interaction between diet and tissue lipids has been further studied by NMR in the liver. The liver has a pivotal role in lipid metabolism. Hepatic receptor-mediated LDL clearance is a major process controlling plasma LDL concentrations, and dietary saturated fat may increase plasma LDL levels by suppression of hepatic LDL receptor activity. The mechanisms underlying this effect are unclear, but it has been suggested that enrichment of hepatic membrane lipids with saturated fatty acids interferes with LDL receptor function.²² Dietary substitution with polyunsaturated fatty acids may then increase hepatic LDL clearance and lower plasma LDL levels, possibly by increasing membrane fluidity.²³ Barnard et al.²⁴ used in vivo $^{13}\text{C}\{^1\text{H}\}$ NMR to examine the hepatic fatty acid profile in rats fed fats with different fatty acid patterns (butter/lard, sunflower oil, fish oil). The resolution of hepatic ^{13}C spectra is limited. The authors therefore used analysis by integration of signals across chemical shift ranges, and suggested expressing results by calculation of unsaturation and polyunsaturation indices (Table 1). A significant dietary effect was shown, with an increasing hepatic content of unsaturated fatty acids and an increasing degree of polyunsaturation as these fatty acids increased in the diet. However, in vitro $^{13}\text{C}\{^1\text{H}\}$ NMR studies of the liver lipid extracts showed a complex relationship,

Figure 3 Olefinic region from natural abundance in vivo coupled ^{13}C NMR spectra of human thigh adipose tissue in (a) vegan and (b) omnivore subjects. Spectra are scaled to the carboxyl signal. The vegan subjects, compared to omnivores, have an increased adipose tissue content of both total unsaturated and polyunsaturated fatty acid carbons (polyunsaturated: 3.45 ± 0.87 versus $2.39 \pm 0.55\%$ of total fatty acid carbons, $p < 0.05$). This reflects at least 3 years' adherence to the vegan diet, which, in the absence of all animal products, is high in polyunsaturated fats (polyunsaturated: 33.13 ± 7.4 versus $25.2 \pm 8.5\%$ of total dietary fatty acids, $p < 0.05$)

with evidence of hepatic metabolism of the dietary fatty acids. Indeed, the liver is a major site of fatty acid uptake, desaturation, synthesis, storage, and secretion.

Investigation of the metabolism of specific dietary fatty acids is a largely unexplored possible future application of ^{13}C NMR spectroscopy. The use of ^{13}C -labeled fatty acids to trace metabolic pathways and kinetic rates is an exciting prospect. These studies may be restricted by the limited

availability of labeled fatty acids, their oxidation after administration, and the sensitivity of the system, given the preexisting strong lipid signals. However, preliminary work has been performed by Cunnane et al.²⁵ and this demonstrated the ability of in vitro $^{13}\text{C}\{^1\text{H}\}$ NMR to detect carbon-specific incorporation of injected $[\text{U-}^{13}\text{C}]$ eicosapentaenoic acid in extracted rat liver lipids.

3.1.2 Deuterium Spectroscopy

There is considerable interest in monitoring lipid turnover in both health and disease. A novel approach to the study of dynamic in vivo tissue lipid metabolism was developed by Brereton et al.⁵ They investigated the use of in vivo ^2H NMR spectroscopy in mice. Administration of D_2O (10% v/v) in the drinking water for 3–4 d allowed the detection of deuterium-enriched tissue lipid resonances in spectra acquired in less than 2 min, as shown in Figure 4(a). The spectra consist of resonances from deuterated water (HOD) and the CHD groups of tissue lipids. Removal of D_2O from the drinking water led to clear changes in the intensity of both signals [Figure 4(b)]. The loss of deuterium from the water signal was significantly faster than from tissue lipids. The loss of deuterium from the lipid resonance was therefore proposed as a noninvasive measure of the rate of fat utilization. This method has since been applied to the study of fat utilization in obesity.

Obesity is one of the most common dietary disorders. It is characterized by excess adipose tissue and elevated levels of plasma nonesterified fatty acids. Furthermore, obesity is known to lead to glucose intolerance and insulin resistance. Fat turnover, as reflected by the levels of plasma nonesterified fatty acids, has been suggested as being implicated in this process. However, the lack of in vivo techniques for measuring fat utilization has greatly hampered progress in this area. Body fat turnover in mouse models of obesity and diabetes mellitus have been studied in vivo using the ^2H NMR technique.²⁶ Brereton et al.²⁶ showed that the rates of fat utilization in obese mice were significantly lower than the rates for nonobese mice (Figure 5) and the induction of diabetes did not affect utilization of fat as a metabolic fuel.

These studies clearly suggest that deuterium NMR spectroscopy provides researchers with a powerful method for noninvasively assessing fat turnover rates.

3.1.3 Proton Spectroscopy

The application of in vivo proton NMR spectroscopy to dietary studies has been rather limited. Indeed, many of the

Table 1 Hepatic Fatty Acid Profile by In Vivo $^{13}\text{C}\{^1\text{H}\}$ NMR Spectroscopy of Rats Fed Different Fats

Dietary Fat	Unsaturation Index ^a	Polyunsaturation Index ^b	Methylene–Methyl/% ^c	Olefinic/% ^c
Butter/lard	0.19 ± 0.04	0.90 ± 0.04	84.1 ± 0.91	15.9 ± 0.91
Sunflower oil	0.24 ± 0.01	1.04 ± 0.04	80.9 ± 0.31	19.1 ± 0.31
Fish oil	0.27 ± 0.01	1.32 ± 0.03	78.9 ± 0.79	21.1 ± 0.79

$p < 0.05$ for all differences between dietary groups.

^aUnsaturation index = olefinic/methylene–methyl signal integration (measures the ratio of unsaturated to saturated fatty acid carbons).

^bPolyunsaturation index = signal intensity at 128.2 ppm ($=\text{C}-\text{C}=\text{C}=\text{C}$)/129.8 ppm ($-\text{C}=\text{C}-$) (measures the ratio of polyunsaturated to monounsaturated + polyunsaturated carbons).

^cOlefinic and methylene–methyl signal area as the percentage of the total fatty acid signal integration (measures the percentage of fatty acid carbons that are unsaturated or saturated, respectively).

Figure 4 (a) Natural abundance ^2H NMR spectrum of a mouse. The CHD resonance is to high field at 1 ppm. Chemical shifts were referenced to the HOD resonance assigned to 4.8 ppm. (b) Deuterium NMR spectra of a mouse following the removal of 10% (v/v) of D_2O from its drinking water. The spectra were recorded (a) 1, (b) 4, (c) 5, (d) 8, (e) 11, (f) 15, (g) 16 and (h) 21 days after the resumption of normal drinking water. Spectrum (i) was recorded prior to the administration of D_2O to the drinking water (Adapted with permission of Heyden & Son Limited from I. M. Brereton, D. M. Doddrell, S. M. Oakenfull, D. Moss, and M. G. Irving, *NMR in Biomed.*, 1989, **2**, 55)

metabolites observed by ^1H NMR spectroscopy do not appear to be affected by diet, with the exception of lipids.⁷ However, due to the small chemical shift range of ^1H resonances and the intense water signal, in vivo ^1H lipid studies have also been restricted. A potentially important alternative application of ^1H NMR is the use of fat imaging to determine quantitative fat distribution in human subjects.²⁷ Regional fat distribution has been correlated to serum lipids and coronary heart disease. Existing methods for measurement of body fat distribution are limited, and fat imaging may in future become the modality of

Figure 5 Plots of ^2H NMR signal intensity as a function of time showing (a) best fit single exponential decay curves for HOD and (b) best fit biexponential function for CHD intensities. The experimental data for control (solid square) and obese (solid circle) mice were used to calculate the body water and fat utilization rates. choice in nutritional and metabolic studies evaluating the risk of coronary heart disease.

3.2 Glycogen Studies

Tissue glycogen values may be a marker of carbohydrate intake and could therefore be of value in dietary studies. Shulman and co-workers²⁸ have developed a ^{13}C NMR technique to provide a direct noninvasive method to measure liver and muscle glycogen concentration in humans. The time course of liver glycogen concentration, following standard test meals, has been carried out by ^{13}C NMR spectroscopy. This opens the possibility of following quantitative changes in glycogen storage with varying diets.^{29,30}

4 HIGH-RESOLUTION NMR SPECTROSCOPY

The unique exploratory capability of NMR spectroscopy has been utilized to investigate the effects of diet on the metabolic profile of body fluids.³¹ The ^1H NMR spectra of urine from

Figure 6 Proton NMR spectra at 500 MHz (aliphatic regions) of urine from 1-month-old rats fed either (a) chow or (b) casein diets. Assignments: Lac, lactate; Ac, acetate; NAc, *N*-acetyl groups of glycoproteins; Suc, succinate; Og, 2-oxoglutarate; Cit, citrate; Dma; dimethylamine; Dmg, dimethylglycine; Cr, creatinine; Cn, creatine; Tau, taurine; NMe, betaine plus trimethylamine *N*-oxide. (Reproduced by permission of Academic Press, Inc. from J. D. Bell, O. Lavender, V. C. Morris, and P. J. Sadler, *Magn. Reson. Med.* 1991, **17**, 414)

rats fed different diets are shown in Figure 6. Clear changes in the metabolic profile of the urine can be observed.¹⁰ Rats fed casein diets for 1 month postweaning did not excrete 2-oxoglutarate, and excreted lower levels of hippurate, succinate, and citrate compared with age/sex-matched rats fed standard chow diets. The acquisition of these spectra took ~2 min. This suggests that high-resolution NMR of urine or other body fluids could be utilized as a fast, multicomponent technique in human studies, for example to screen rapidly for multiple metabolic effects or to check dietary compliance.

Plasma concentrations of LDLs and high-density lipoproteins (HDLs) are well established markers for coronary heart disease risk assessment. Standard methods for quantification and compositional analysis of plasma lipoproteins require laborious and time-consuming physical separation based on particle size, density, or apolipoprotein content. Bell et al. have shown that NMR spectroscopy can be readily applied to study alterations in plasma lipoproteins associated with dietary manipulation, both in intact plasma or in the separated lipoprotein classes.^{11,12} The effects of fish oil supplementation on the ¹H NMR profile of lipoproteins in intact plasma are illustrated in Figure 7. Changes in composition are shown by a new lipid resonance (peak 2A) arising from fish oil $n - 3/\omega - 3$ fatty acids incorporated into plasma lipoproteins, while the methylene $[-(\text{CH}_2)_n-]$ signal (peak 3) is markedly reduced. Furthermore, T_2 analysis of the lipid resonances showed that these changes in lipid composition of the LDL particles are accompanied by alteration in the structural characteristics of these particles.

Figure 7 Expansions of spin echo ¹H NMR spectra of intact human plasma (a) before and (b) after 7 d of fish oil supplementation. Assignments: peaks 1 and 2, terminal $-\text{CH}_3$ group from LDLs/HDLs and very low-density lipoproteins (VLDLs), respectively; peak 3, $-(\text{CH}_2)_n-$ of VLDLs. Peak 2A arises from $n - 3/\omega - 3$ fatty acids incorporated into plasma lipoproteins. (Reproduced by permission of Birkhauser Verlag from P. C. Dagnelie, J. D. Bell, M. L. Barnard, and S. C. R. Williams, in 'Omega-3 Fatty Acids: Metabolism and Biological Effects' ed. C. A. Drevon, I. Baksaas, and H. E. Krokan, Birkhauser Verlag, Basel/Switzerland, 1993, p. 27–34)

At present, sophisticated computer deconvolution methods (line-fitting analysis) are being developed to identify and quantify lipoprotein fractions in the ¹H NMR spectra of intact plasma samples (500 μl) within minutes.^{32,33}

In this article we have reviewed the current state of NMR spectroscopy as applied to dietary studies. It is clear that this is a relatively new area of NMR research. However, it offers many exciting prospects for future research into diet and nutrition in humans.

1 INTRODUCTION

From a chemical structure viewpoint, the building blocks of food are water, carbohydrates (particularly polysaccharides), lipids, and proteins. From the viewpoint of physical chemistry or materials science, these substances are combined together in a rich variety of structures ranging from essentially pure liquids, to solutions, gels, emulsions, foams, suspensions, solids, and porous media containing large amounts of water (as in fruit) and others which are dry or nearly so (e.g. biscuits). Furthermore, the molecules themselves contain one or more NMR-active nuclide (e.g. ^1H , ^2H , ^{13}C , ^{23}Na , or ^{31}P). As a result, foods are amenable to investigation by essentially the entire array of NMR methodology, including both solution- and solid state spectroscopy and NMR imaging.

2 EQUIPMENT

Whilst most of the NMR research in food science has been performed using high-resolution or solid state instrumentation, many industrial applications use low-cost, benchtop instruments specifically designed for a limited range of highly optimized applications.¹ The most widely used device is made by Bruker and operates at 10 and 20 MHz for samples up to 18 mm in diameter. Typical applications using such systems involve the determination of the solid-to-liquid ratio of fats, or the quantitation of water in foods. NMR imaging of food has mainly been done using 31-cm bore magnets operating at 2 T, or whole body clinical systems. The key technical requirement is that the gradient system be capable of implementing sequences with spin echo times of 5 ms or less.

3 SPECTROSCOPY

The most widespread use of proton spectroscopy in the food industry continues to be the determination of the solid-to-liquid ratio of fats.^{2,3} The technique exploits the differences in the spin-spin relaxation times of protons in liquid and solid

domains; such measurements are routinely performed using low field strength magnets. This is a rapid and reliable method for determining the oil and water content of seeds and can be used in breeding experiments and in optimizing storage and processing conditions.⁴ Much of the early work on food involved ^1H relaxation studies of water^{5,6,7} which gave insight to the location and mobility of water associated with foods, especially carbohydrates such as starch, and proteins. The diffusion coefficients of water and lipids can be determined by pulse field gradient NMR.⁸ These experiments can also be used to investigate restrictions to free diffusion, and thereby allow the size of water domains in complex structures to be estimated (e.g. the size of water droplets in emulsions).

Measurements made at high field strengths of the deuteron resonances of wine and fruit juices have recently been used as a new approach to 'food authentication'. This elegant approach, called site-specific natural isotope fractionation (SNIF) NMR, is based on the fact that the distribution and ratio of ^1H and ^2H isotopes of low molecular weight molecules such as glucose, ethanol, and acetic acid depend on their biochemical origin.⁹ For example, SNIF NMR can differentiate between ethanol produced from the sugar of grains and that from grape juice. Consequently, addition of beet or cane sugar to supplement a low sugar content grapes can be detected.

High field strength, highly homogeneous magnets are necessary for high-resolution, solution state NMR. This method is used to elucidate chemical structure. Typically, ^1H and ^{13}C spectra are acquired; however, ^{31}P , ^{23}Na , and ^{15}N nuclei are also useful in certain situations. For example, ^{31}P NMR is used to investigate metabolism in vivo as well as allowing cellular pH to be estimated.¹⁰ Solid samples usually give rise to very broad featureless spectra; however, it is possible to acquire high-resolution spectra by cross polarization, magic angle spinning (CP MAS) NMR. Solution- and solid state ^{13}C NMR have been used to study whole intact seeds.^{11,12} ^{15}N cross-polarization spectra have also been reported; for example, soya beans grown in ^{15}N enriched ammonium nitrate and amino acids have been studied.¹³ High resolution solution- and solid state ^{13}C spectroscopy can be combined with ^1H relaxation studies to elucidate the microdynamics of the various domains in complex heterogeneous systems such as wheat gluten.¹⁴

4 IMAGING

It is relatively easy to obtain magnetic resonance (MR) images from most food products,¹⁵⁻²¹ providing that the container is transparent to radiofrequency waves and is free of ferromagnetic components. Consequently, it is feasible to study food storage in the marketing container completely noninvasively. In addition to obtaining well-resolved NMR images of the internal structure of foods, the food scientist would like to make measurements from the images, for example correlating image intensity with a physical parameter such as water content, diffusion coefficient, or flow velocity. The ease with which a quantitative image²² can be generated depends not only on the quantity of the NMR species present and their ^1H relaxation times, but also on the value of the echo time available. Thus it is relatively straightforward to produce proton density T_1 and T_2 maps for high water content foods such as fruit, vegetables, and many dairy and meat

products. Furthermore, since the water protons have relatively long T_2 values, their linewidths are sufficiently narrow that at 2T or more chemical shift resolution between water and lipid resonances can be achieved by selective excitation.²³ By comparison, low moisture content foods, such as pasta, generally give such broad water resonances that the resolution of water from lipid signals is impossible; in most biscuits, for example, the MR image is dominated by the signal from the lipid.

Given the known dependence of NMR parameters on the physicochemical environment of the water and lipid molecules, it is clear that MRI should provide invaluable insight to structural changes that accompany food processing.^{24,25} Examples to date include baking, freezing/thawing, drying, hydration, curing, heating in thermal or microwave ovens, or frying in oil. In addition, it is possible to visualize and quantitate the flow of liquids, including suspensions.²⁶ The circulation and diffusion of water within wheat grains has also been studied.^{27,28}

MRI of fruits and vegetables provides excellent definition of the internal architecture of the object. Importantly, processes which disrupt the cellular structure can generally be visualized with great clarity. For example, bruising of fruit¹⁶ and freeze/thawing²⁹ leads to a change in image contrast in the sample. Both these effects reflect two important changes. First, there is the local change in water distribution from intra- to intercellular space, which displaces air and thereby changes the distribution of susceptibility variations in the material.³⁰ Second, for some systems (e.g. celery), there can be anisotropy of diffusion rates and distances in the fresh material which is disrupted by cellular damage.

As the food system becomes 'drier', the T_2 value of the water protons decreases. Consequently, it becomes progressively more difficult to perform any form of MRI measurement, let alone determine water content. For such systems, one-dimensional projections of spin density or ^1H relaxation times obtained without gradient switching can provide a one-dimensional map of water distribution. Depending on the physical shape of the object, such a projection may provide invaluable insight; for example, following the migration of water during the later stages of drying of spaghetti.

A simple example of chemical shift resolved imaging involves visualizing the separation of cream from whole milk. A valuable application is the ability to measure by this technique the water and lipid content in high moisture content samples such as sunflower oil emulsions and fresh meat.³¹ An important use of chemical shift resolved imaging is mapping of the water and fat content of processed foods before, during, and after cooking. For example, chemical shift resolved studies of pork pies, fish in batter, and pizza, that were cooked in a microwave or thermal oven show distinct differences in the fat and water images related to their cooking regime. A similar study of the fat uptake during frying of chips is also revealing. In contrast, it is not possible to resolve the water and fat signals in an image of a biscuit; nevertheless, even in the hardest and driest of biscuits it is relatively easy to map the lipid distribution. The signal intensity of the MR image intensity from the lipid in chocolate¹⁹ is very sensitive to the precise crystal, or liquid crystal, morphology of the lipid, and hence of the thermal treatment used to anneal the chocolate into a stable form which has desirable 'mouth feel'.

5 FUTURE PROSPECTS

The successful use of benchtop NMR spectrometers as a source of analytical data in the food laboratory is an encouraging augury for their wider use on the factory floor. Such applications will demand further improvements in 'ruggedization', together with interfacing either to automated batch sampling or, more likely, to continuous online, flow sampling. Fortunately, the technical components for such an instrument are already available, including low cost permanent magnets with a box or C-shaped structure, through which either a pipe or conveyor belt can pass. Furthermore, the development of 'inside-out NMR' in which the magnetic field is external to the magnet, means that it is feasible to construct a complete NMR magnet and probe which could be dipped into a container of food. Although the prospects for shop floor applications of NMR imaging are less obvious at this time, it is clear that demand will come from both increasing quality control standards and the need to develop new foods and optimize their processing and storage. A stimulus for this development is public demand for healthy, quality, ready-made foods which have low fat content and can be cooked in microwave ovens, yet have the texture and appeal of their traditional equivalents.

1 INTRODUCTION

Why is there a need for metal substitution? This approach in the investigation of metalloproteins has been, and is being, widely used in order to exploit the favorable spectroscopic properties of a suitable metal ion.^{1–6} With regard to NMR, paramagnetic metal ions are used because they produce additional contributions to both the shift and relaxation parameters of the nuclei coupled to them^{7–9} (see *Electron–Nuclear Hyperfine Interactions, Electron–Nuclear Multiple Resonance Spectroscopy*). The effect on the shift can be of sufficient size that, under certain circumstances, the signals due to such nuclei are well resolved from those of the rest of the protein. This increases the spectral resolution for those nuclei coupled with the paramagnetic center and, when the latter is in the active center of the molecule, very valuable biochemical information can be obtained.

Paramagnetic metal ions can be exploited as relaxation probes or shift probes depending essentially on their electron relaxation times. When the electron relaxation times are long, NMR lines are broad and the metal ion acts as relaxation probe (see *Paramagnetic Relaxation in Solution*). When electron relaxation times are short, NMR lines are relatively sharp and the metal ion acts as a shift probe. We are only interested in shift probes here.

In order to have little line broadening, the coupling between the electron spin S and the nuclear spin I should be modulated by correlation times τ_c in the range 10^{-11} – 10^{-13} s, depending on the number of unpaired electrons. As the rotational correlation times, τ_r , in macromolecules with molecular weights in the range 6000–50 000 are of the order of 10^{-8} – 10^{-9} s, it follows that the possibility of obtaining high-resolution NMR spectra depends on the efficiency of the electron relaxation of the metal ion.

If a diamagnetic metal ion (typically Zn^{2+} but also Ca^{2+} , Cd^{2+}) or a paramagnetic metal ion with unfavorable relaxation

properties (Cu^{2+} , Mn^{3+} , Mn^{2+} , high-spin Fe^{3+}) is present in a metalloprotein, its replacement with another metal ion with a similar ionic radius and similar coordination properties but favorable electron relaxation times gives rise to a metal-substituted protein whose metal ion surroundings can be investigated by NMR. Because of their favorable electronic properties with respect to NMR and their coordination chemistry, high-spin Co^{2+} and Ni^{2+} are among the most used and most suitable metal ions for substituting other metal ions, particularly Zn^{2+} . They are always high spin in tetrahedral geometry and, for Ni^{2+} , in octahedral geometry. Penta-coordinate ions are often high spin with oxygen and nitrogen donor atoms. In addition, octahedral Co^{2+} is often high spin.

The goal in the use of metal substitution is that of obtaining local information on the metal site through the analysis of the hyperfine (paramagnetic) shifts and of the nuclear relaxation rates of the nuclei of the metal ion ligands and of nearby residues. Furthermore, in the presence of inhibitors and pseudosubstrates, the NMR parameters provide information on the rearrangements induced by the binding of the molecule to the protein.

2 THE ELECTRONIC PROPERTIES OF HIGH SPIN COBALT(II) AND NICKEL(II) IONS

The Co^{2+} ion is a d^7 metal ion, the free ion having the ground state ^4F . In octahedral symmetry the ground state splits into $^4\text{T}_{1g}$, $^4\text{T}_{2g}$, $^4\text{A}_{2g}$, the ground state being $^4\text{T}_{1g}$. In the presence of low-symmetry components, spin–orbit coupling provides six Kramers doublets which are slightly separated. Conversely, in tetrahedral symmetry the ground state is the nondegenerate $^4\text{A}_2$ state. Hence, in O_h symmetry, low energy levels are available while in T_d symmetry the ground state is nondegenerate and excited levels are higher in energy. The presence of low-lying excited states in octahedral symmetry, arising from the splitting of the $^4\text{T}_{1g}$ ground level due to low-symmetry components, contributes to making electron relaxation more efficient in this geometry with respect to tetrahedral coordination and hence to shortening the electron relaxation times. Consequently, the τ_s values of a metal ion are dependent on the coordination geometry of the metal ion itself. For Co^{2+} , τ_s values of 10^{-13} – 10^{-12} s have been found for hexa-coordinate ions, of around 10^{-12} s for penta-coordinate, and of around 10^{-11} s for tetrahedral chromophores.⁹

In the case of the Ni^{2+} (d^8) metal ion, the splitting of the free ion term ^3F provides a nondegenerate ($^3\text{A}_{2g}$) ground state for octahedral chromophores and, therefore electron relaxation mechanisms are not very efficient. In contrast, in tetrahedral chromophores a degenerate ($^3\text{T}_2$) ground state is available and therefore more efficient electron relaxation pathways are operative. Thus τ_s values of 3×10^{-12} s have been estimated for $\text{Ni}(\text{H}_2\text{O})_6^{2+}$ ⁹ while tetrahedral Ni^{2+} experiences τ_s values in the range 10^{-12} – 10^{-13} s at low magnetic fields. As a consequence, Ni^{2+} is a better probe for metal substitution in tetrahedral systems, while Co^{2+} is more suitable for penta- and hexa-coordinate chromophores. In the next sections we will provide examples of metalloproteins in which the native metal ion has been replaced with Co^{2+} and/or Ni^{2+} and we will illustrate the valuable information thus obtained.

3 METAL SUBSTITUTION AND NMR PARAMETERS

One large and relevant class of metalloproteins is that of the zinc enzymes^{1–3} (see *Carbonic Anhydrase*; *Zinc Fingers*). Due to the similar coordination properties of the two metal ions, in many cases the cobalt(II)-substituted zinc proteins retain most of the biological properties of the native protein. Usually, substitution with Ni²⁺ produces derivatives with reduced biological activity. In addition, Fe²⁺, Mn²⁺, and Cu²⁺ have been replaced by Co²⁺ and also sometimes by Ni²⁺.^{6,10}

The extent of hyperfine shifts on the nuclei of residues directly bound to the paramagnetic metal ion depends on the metal ion itself and on the nature of the ligands (see *Electron–Nuclear Hyperfine Interactions*). The contact contribution is related to the spin delocalization on the ligand nuclei, while the pseudocontact contribution depends on the magnetic susceptibility anisotropy of the metal ion which, in turn, is determined by the nature of the metal ion and by its coordination geometry. Table 1 reports the range of observed chemical shifts for protons of various ligands to cobalt(II) and nickel(II) in different coordination geometries and in biological molecules. In a few cases the two contributions, i.e. contact and pseudocontact contributions, have been factored out. However, for the nuclei of ligands directly coordinated to the metal ion, the contact contribution is, by far, the dominant. From Table 1, it appears that shifts of up to +300 ppm have been observed for the H- β protons of cysteines coordinated to Co²⁺ and Ni²⁺.

The pseudocontact contribution to the shift in penta- and hexa-coordinate Co²⁺ chromophores is considerably larger than in tetrahedral coordination. The opposite occurs for Ni²⁺, where large pseudocontact shifts are observed for tetrahedral coordination and negligible pseudocontact contributions are observed in hexa-coordinate systems. The presence of sizable pseudocontact contributions to the shift causes the appearance of several relatively sharp resonances in the +25 to –20 ppm region of penta- and hexa-coordinate Co²⁺ systems arising from protons up to 7–8 Å apart from the metal ion and not belonging to metal-coordinated residues. The hyperfine shifted signals can be investigated via 1D NOE (see *Nuclear Overhauser Effect*) and/or 2D NMR spectroscopy in order to assign them unambiguously.

The increase in the nuclear relaxation rates due to coupling with the paramagnetic metal center occurs essentially through dipolar coupling for protons, while contact coupling can also appreciably affect nuclear relaxation in the case of other nuclei. In macromolecules, in the absence of chemical exchange, both couplings are modulated by the electron correlation times of the paramagnetic center.

A limitation in the application of high-resolution NMR in cobalt(II)- and nickel(II)-substituted proteins arises from the occurrence of substantial line broadening with increasing magnetic fields. Indeed, the contribution to transverse relaxation due to coupling of the nuclei with the static magnetic moment (Curie spin relaxation) (see *Paramagnetic Relaxation in Solution*) must be taken into account.¹¹ This contribution can be relevant in metalloproteins, and its relevance increases with the number of unpaired electrons and, consequently, with the magnetic moment of the metal ion.⁹ The spin state $S = \frac{3}{2}$ of cobalt(II) produces a sizable Curie spin relaxation contribution to the linewidth at high magnetic fields. The Curie spin relaxation term is modulated by τ_r and, therefore, increases with increasing molecular size. Furthermore, it depends on the square of the magnetic field. Hence, in unfavorable cases, i.e. large molecules at high magnetic fields, this contribution easily dominates transverse relaxation. As an example, consider a cobalt(II)-substituted protein of molecular weight 30 000 with τ_r of 1×10^{-8} s and a τ_s value of 5×10^{-12} s for Co²⁺. For a proton 5 Å from the metal ion, the overall (dipolar + Curie) linewidth at 200 MHz is 78 Hz and the Curie spin contribution is 28 Hz (i.e. the latter accounts for 37% of the overall linewidth). At 600 MHz the overall linewidth for the same proton is 293 Hz and the Curie contribution is 249 Hz (85% of the overall linewidth). This example shows why, due to the strong field dependence of signal linewidths in cobalt(II)-containing proteins, the use of lower field spectrometers can be convenient and, sometimes, necessary.

The ¹H NMR spectra of an inhibitor (thiocyanate) adduct of cobalt(II)-substituted carbonic anhydrase (molecular weight, 32 000) (see later), shown in Figure 1 at different magnetic fields, provide a nice example of the above considerations. It can be seen, for example, that signal A' is only detectable at 90 MHz, while signal E is still observable at 200 MHz but is broadened beyond detection at 600 MHz.

Two-dimensional experiments have been carried out on several cobalt(II)-substituted and nickel(II)-substituted macromolecules (see *Multidimensional Spectroscopy: Concepts*), despite the presence of a paramagnetic center (see later for examples). In these experiments the mixing times were relatively short with respect to the relaxation of the nuclei but long enough such that transfer of magnetization or coherence occurred. The recycle times can also be set to be relatively short in order to increase the number of transients in the experiment time, thus improving the signal-to-noise ratio.

Recently, it has been pointed out¹² that cross correlation between dipolar relaxation and Curie spin relaxation [which can be sizable in cobalt(II)-containing macromolecules] can

Table 1 Chemical Shift Ranges (ppm) Experienced at Room Temperature in Solution by Protons of Residues Bound to a Cobalt(II) or a Nickel(II) in the Active Site of Metalloproteins with Different Coordination Geometries

Coordination geometry	Ligand and proton type			
	Cys G- β	His <i>ortho</i> -like	His <i>meta</i> -like	Asp H- β , Glu H- γ
<i>Cobalt(II)</i>				
Tetrahedral	300–200	150–40	70–35	80–30
Penta-coordinate	300–200	130–30	80–50	
Octahedral			70–50	
<i>Nickel(II)</i>				
Tetrahedral	300–150		80–20	
Penta-coordinate	240–190		80–35	

Figure 1 ^1H NMR spectra of the thiocyanate adduct of cobalt(II)-substituted carbonic anhydrase recorded at different magnetic fields: (a) 90 MHz, (b) 200 MHz, (c) 600 MHz. The spectrum shown in (a) was recorded in D_2O in order to detect the broad A' signal otherwise covered by the A signal. 'Hatched' signals disappeared when the spectra were recorded in D_2O

give rise to cross peaks in COSY experiments even in the absence of scalar interaction between the protons. This mechanism is called relaxation allowed coherence transfer (RACT); it is absent in in-phase COSY or superCOSY experiments (see *Relaxation Processes: Cross Correlation and Interference Terms*).

4 COBALT(II)-SUBSTITUTED PROTEINS

The first spectrum of a cobalt(II)-substituted protein for which an attempt at sequence specific assignment was reported was that of cobalt(II)-substituted carbonic anhydrase (CA).¹³ CA is a zinc enzyme (see *Carbonic Anhydrase*) which catalyzes the hydration of carbon dioxide.¹⁴ The zinc ion is bound to three histidines with a roughly tetrahedral geometry. The fourth coordination position is accessible to the solvent or occupied by a water molecule. The latter molecule is transformed into a hydroxide group with a relatively low pK_a value. Substitution of the native zinc ion with cobalt(II) maintains about 50% of the enzymatic activity of the native protein. The cobalt(II)-substituted protein provides an NMR

spectrum which shows some well resolved, high-frequency-shifted signals. They are due to the histidine protons in *meta*-like positions with respect to the cobalt. Some of these signals have been readily assigned to the NH protons of the histidine rings due to their exchange with the bulk solvent.

As can be seen from the spectrum of the native cobalt(II)-substituted protein, reported at the bottom of Figure 2, the ^1H NMR signals due to the protons of the cobalt ligands are relatively broad (ca. 300 Hz at 200 MHz) and shifted within a relatively narrow shift range (+53 to +63 ppm). In addition, very few signals of protons not belonging to metal ligands are resolved outside the diamagnetic envelope. This is due to the tetrahedral geometry of the cobalt ion in the native form of this enzyme, which is characterized by small magnetic anisotropy and relatively long electron relaxation times. Hence the pseudocontact contribution to the shift is small and only protons belonging to the metal ion ligands experience sizable hyperfine shifts. This means that information remains substantially limited to the coordinated residues.

When inhibitors bind cobalt(II) without displacing the coordinated solvent molecule, a five-coordinate adduct is obtained in which cobalt(II) experiences a much larger magnetic anisotropy and shorter electron relaxation times. This means that several protons belonging to residues close to the cobalt ion, but not directly coordinated to it, are shifted substantially and well resolved outside the diamagnetic envelope. Furthermore the lines are sharper (ca. 200 Hz at 200 MHz) than in the spectrum of the native form. ^1H NMR spectra of adducts with several inhibitors are reported in Figure 2. On these spectra, classical NMR techniques for spectral assignment such as NOE (see *Nuclear Overhauser Effect*) and 2D NMR experiments (*COSY Two-Dimensional Experiments; Multidimensional Spectroscopy: Concepts; NOESY*) have been performed. They have led, for the adducts with nitrate, perchlorate and thiocyanate, to the assignment of the signals of the metal ligands and of several residues present around the active site.^{13,16} Some of these assignments have been confirmed by analysis of the spectra of samples produced with selectively deuterated amino acids.¹⁶

The assignment of several protons experiencing only pseudocontact shifts has allowed the calculation, using a best-fitting procedure and the knowledge of the X-ray structure of the protein, of the anisotropy and the orientation of the magnetic susceptibility (χ) tensor. The latter information is relevant for the knowledge of the electronic structure of the cobalt ion in the adduct. Furthermore, it allows the calculation of the shifts for all the protons sensing some coupling with the metal ion, which can help in further assigning other signals.^{13,16}

Extensive studies have also been performed on cobalt(II)-substituted carboxypeptidase (CPA) which is a zinc enzyme¹⁷ where the five-coordinate metal ion is bound to two histidines, a water molecule, and a bidentate glutamate. Cobalt substitution increases the enzymatic activity of native CPA. The protein is soluble only at high ionic strengths, i.e. in viscous solutions. This provides long τ_r values and consequently large line broadening due to Curie spin relaxation. Indeed, no high-field NMR experiments have been performed on this system.

Despite these problems, cobalt(II)-substitution in CPA has provided useful information on the local structural features at the metal ion and on the enzyme reactivity. The ^1H NMR

Figure 2 ^1H NMR spectra at 200 MHz of native and some anion adducts of cobalt-substituted carbonic anhydrase. 'Hatched' signals disappeared when the spectra were recorded in D_2O . (Reproduced by permission of Kluwer Academic Publishers from L. Banci, I. Bertini, C. Luchinat, and J. M. Moratal, in *Enzymatic and Model Carboxylation and Reduction Reactions for Carbon Dioxide Utilization*, eds. M. Aresta and J. V. Schloss, 1990, pp. 181–197)

spectrum of CoCPA (optimal field 90–200 MHz) shows three relatively sharp signals which have been assigned, through 1D NOE measurements, to *meta*-like protons of the two histidines. Two broader peaks have also been observed in the ^1H NMR spectrum of CoCPA and assigned, on the basis of their T_1 and T_2 values, to the two H- γ protons of the Co^{2+} -bound glutamate.

Information on the biochemistry of the enzyme was obtained by monitoring the changes in the ^1H NMR spectrum upon addition of inhibitors and substrate analogs.¹⁸ For instance, it has been observed that some inhibitors such as carboxylic acids bind the enzyme in a 2:1 ratio. The first inhibitor molecule binds through its carboxylate group to an Arg residue (Arg-145) present in the catalytic cavity. The binding of this molecule in the cavity breaks the strong H-bond present between the zinc-bound water molecule and a Glu residue (Glu-270) present in the cavity, and makes the water molecule easily displaceable by a second molecule of inhibitor which binds the metal ion directly.

Cobalt substitution has been successfully performed on Cu_2Zn_2 superoxide dismutase (SOD hereafter).¹⁹ This enzyme contains two metal centers connected by a histidine bridge. Cobalt(II) can substitute zinc in its native site. Several systems, with no metal or with diamagnetic metal ions [Ag(I) or Cu(I)] in the copper site, have been investigated with the aim of characterizing the zinc ion-binding site. In such systems, cobalt(II) is coordinated by three histidines and a unidentate aspartate. The spectra of such derivatives are all similar to each other. Eight signals are hyperfine-shifted in the high-frequency region, i.e. the three *meta*-like exchangeable HN- ϵ 2, the three nonexchangeable H- δ 2 protons of the imidazole rings and the signals of the two H- β protons of the bound aspartate. The observation of three HN signals in the case of $\text{Cu}_2\text{Co}_2\text{SOD}$ provided the first direct evidence that the imidazole bridge between the two metal ions is broken when the copper ion is reduced.²⁰ Indeed, this finding is particularly remarkable in the light of recent X-ray studies on the reduced form of the native ($\text{Cu}_2\text{Zn}_2\text{SOD}$) protein which show, in the solid state, no bridge-breaking in this form of the enzyme. The spectrum of $\text{Cu}_2\text{Co}_2\text{SOD}$ has been investigated through 1D NOE and 2D NMR experiments at different magnetic fields²⁰ in order to: (i) assign the far-hyperfine-shifted signals (1D NOE at 200 MHz), (ii) assign the signals of residues belonging to the active site but not bound to the Co^{2+} ion (2D NOESY, 600 MHz), and (iii) use the pseudocontact shifts [available because of the assignment at point (ii)] to obtain information on the χ tensor anisotropy and directions of the Co^{2+} ion in the zinc site, analogous to the case of cobalt(II)-substituted CA.

An interesting example of the utility of metal substitution in proteins with large molecular weight (MW) is provided by cobalt substitution of the native zinc ion in liver alcohol dehydrogenase (LADH), a dimeric protein of MW ca. 80 000. The metal ligands are two cysteines, one histidine, and a water molecule. Even in the case of this large molecule, the signals of the two Cys H- β protons and of the three histidine protons (including the *ortho*-like proton) have been observed. Of course, the higher the molecular weight, the larger is the Curie spin relaxation term. Hence, such signals are best detected at 60 MHz!²¹

Another example of a large protein for which cobalt substitution turned out to be useful with respect to obtaining information on the metal site is alkaline phosphatase (AP). AP is a large dimeric protein (MW 94 000) consisting of two identical subunits. Each contains three metal binding sites; in the native form two of these sites bind zinc while the third is specific for magnesium. Zinc has been substituted by cobalt(II) in its binding sites. Information on the metal ion ligands as well as on the metal uptake pathways has been obtained even on this large molecule.²²

One of the most recent applications of cobalt(II) substitution has been performed on zinc finger peptide CP-1.²³ At variance with the previously reported cases, zinc finger proteins have already been studied extensively through high-resolution ¹H NMR in their native form due to their relatively low molecular weight (see *Zinc Fingers*). However, cobalt(II) substitution has provided useful insights. Knowledge of the pseudocontact shifts of several resonances in the cobalt(II)-substituted protein has led the authors to calculate the χ tensor of the system. For a correct determination of the pseudocontact shifts, it is important to know the diamagnetic contributions to the shifts. The latter have been obtained by taking advantage of the assignment of the signals of the native protein.

Zinc proteins are not the only systems in which cobalt(II) substitution was successfully attempted. Iron has been substituted by cobalt(II) in several systems (see *Iron—Sulfur Proteins*, *Nonheme Iron Proteins*, *Transferrins*). Indeed, in the absence of magnetic coupling with fast relaxing metal ions and in nonheme proteins, both high spin iron(III) and high spin iron(II) give rise to relatively broad ¹H NMR signals.⁹ For this reason, although the ¹H NMR spectra of the iron(III)-containing protein Isopenicillin Synthase (INPS) have been recorded and several hyperfine-shifted signals observed, cobalt(II)-substituted INPS has been prepared in order to obtain hyperfine-shifted signals sharp enough to perform 1D NOE experiments. These have led to the tentative proposal of the structure of the active site (no X-ray data are available) and of a catalytic mechanism.²⁴ Similar considerations hold also for the signal linewidths in rubredoxin (Rd) (see *Iron—Sulfur Proteins*) where the iron ion has a tetrahedral geometry and is coordinated to the sulfur atoms of the four cysteines. In this system, cobalt(II) and nickel(II) substitution was also performed. The ¹H NMR spectra are characterized by sharp and well-resolved signals, although no firm assignment is available for the spectra.²⁵

Metallothioneins (MT) constitute a class of small proteins containing clusters of the type Cd₄S₁₁ and Cd₃S₉. Titration of the apoprotein with cobalt(II) has been followed using NMR and has allowed the authors to study the uptake pathway of the metal ions. The Co₃S₉ cluster was first formed. The protein containing this cluster shows broad hyperfine signals, probably because the Co₃S₉ cluster experiences some fluxionality that broadens the lines beyond detection.²⁶ The ¹H NMR spectrum of the fully-substituted protein (Co₇MT) shows a large number of sharp, very high-frequency-shifted signals arising from the H- β protons of the cobalt(II)-coordinated cysteines. Such signals are shifted by up to +400 ppm. Detection of ¹H NMR signals at 600 MHz over such a large spectral width required the use of a fast ADC (9-bit digitizer over 10 MHz) (see *Spectrometers: A General Overview*). An extensive pairwise assignment of the H- β cysteine protons was performed by 1D NOE and 2D NOESY experiments as well as by observing the temperature dependence of the shifts, interpreted on the basis of a magnetic coupling scheme among the metal ions.²⁶

Substitution of the native iron(III) ion in transferrins (TRN, MW 90 000) (see *Transferrins*) with cobalt(II) provided derivatives which showed, at 90 MHz, several high-frequency-shifted signals despite the large molecular weight of the protein.²⁷ The protein contains two metal binding sites which are not equivalent as revealed by ¹H NMR spectra. The observed signals were attributed to the presence of histidine and tyrosine residues as ligands to the metal ions. This example

shows that the presence of a suitable metal ion can aid the characterization through NMR of even large proteins.

The blue copper protein azurin (Az) (see *Copper Proteins*) has been investigated through ¹H NMR of the cobalt(II)- and nickel(II)-substituted derivatives.²⁸ The metal ion is penta-coordinate, its ligands being two histidines, one cysteine, one methionine, and the oxygen of the carbonyl group of a glycine residue. This protein has a relatively small molecular weight (16 000) which makes the Curie spin relaxation less efficient than in the systems previously described. The signals of the protons of the metal ion ligands are therefore relatively sharp. The H- β proton signals of the coordinated cysteine are shifted by more than +200 ppm while the signals of the ring protons of the two histidines fall in the usual 60–30 ppm region. The signals of two geminal proton pairs, which were tentatively assigned to the H- α protons of the metal-coordinated glycine and to the H- γ protons of the coordinated methionine, are observed with one signal shifted at low frequency and its geminal partner at high frequency for both pairs.²⁹ This behavior has not yet been rationalized, but it could be due to the different M–S(O)–C–H dihedral angles experienced by the two protons in each pair. This would make the spin density different on each of the two protons.

Experiments involving nuclei other than protons are much less common, even if quite promising. Heteronuclear multiple quantum coherence (HMQC) experiments (see *Heteronuclear Shift Correlation Spectroscopy*) on ¹⁵N-enriched samples have been performed on cobalt(II)-substituted CA,⁶ and several scalar ¹⁵N–¹H couplings between residues close to the cobalt ion have been detected.

5 NICKEL(II)-SUBSTITUTED PROTEINS

There are several examples in which nickel substitution has been performed on the same proteins where the native metal ion has also been replaced by cobalt. As previously discussed, nickel(II) is, in principle, more suitable for the investigation of tetrahedral centers and less useful in the case of hexa-coordinate chromophores. Indeed, the nickel(II) ion in NiCPA in the presence of two moieties of D-phenylalanine induces broad lines and small pseudocontact shifts due to the small magnetic anisotropy.³⁰ In contrast, the ¹H NMR spectrum of NiCPA without any inhibitor shows sharp lines for the *meta*-like protons of the bound histidines,³⁰ the opposite of that observed for cobalt(II)-substituted CPA.

Nickel(II)-substituted CA has also been investigated through ¹H NMR, although the interest in such derivatives from the biochemical point of view is limited due to the severe reduction of activity. For those adducts of NiCA for which NMR studies have been performed, information similar to that obtained upon cobalt(II) substitution was achieved.³¹

In the case of tetrahedral chromophores such as Fe^{III}Rd and Cu^{II}Az, nickel(II) substitution produces derivatives with narrower lines relative to the corresponding cobalt(II) substituted derivatives.³² In the case of zinc fingers, also, nickel(II) substitution produces narrower hyperfine-shifted ¹H NMR signals with respect to those observed in the cobalt(II) derivative. However, no assignment of the hyperfine-shifted signals has been attempted for the nickel derivative.³³

Finally, a derivative with a nickel(II) in the zinc site of SOD and no metal in the copper site has been prepared and

characterized through NMR,²⁰ again obtaining information similar to that on the analogous cobalt(II) derivative.

6 COBALT(II)- AND NICKEL(II)-SUBSTITUTION IN MAGNETICALLY COUPLED DIMERS

Cobalt(II) and nickel(II) are not only efficient probes for NMR investigation in themselves, but they can also drastically reduce the electron relaxation rates of a slow-relaxing metal ion through magnetic coupling.⁹ This coupling allows the slow-relaxing ion to relax through the efficient mechanisms of the fast-relaxing metal ion. The effect depends on the extent of the magnetic coupling constant; in the limit of $J/\hbar \gg \tau_s^{-1}$ (where τ_s is referred to the fast-relaxing metal ion) the relaxation rate of the slow-relaxing metal ion approaches that of the fast-relaxing ion^{9,34} (see *Paramagnetic Relaxation in*

Solution, Relaxation Theory: Density Matrix Formulation). Under such conditions, even the signals of nuclei coupled to a slow-relaxing metal ion which, when isolated, would induce a dramatic increase in the linewidth, can be easily detected because they are sharp enough for the application of standard high-resolution NMR techniques.

An elegant application of the above considerations is provided by the replacement of native zinc ion in $\text{Cu}^{\text{II}}_2\text{Zn}_2\text{SOD}$ by cobalt(II) and nickel(II). The copper(II) ion is characterized by τ_s values of the order of 10^{-9} s which produce a dipolar contribution to the linewidth of a proton at 5 Å from copper (as for the *meta*-like protons of the coordinated histidines) of 2000 Hz. However, the magnetic coupling of copper with cobalt(II) or nickel(II), which relax much faster than copper(II), produces a drastic reduction of the relaxation times of the latter metal ion. The ^1H NMR spectra of $\text{Cu}_2\text{Co}_2\text{SOD}$ and of $\text{Cu}_2\text{Ni}_2\text{SOD}$ are reported as the upper traces in Figure 3.²⁰

Figure 3 600 MHz NOESY spectra of $\text{Cu}_2\text{Co}_2\text{SOD}$ (a) and $\text{Cu}_2\text{Ni}_2\text{SOD}$ (b) in the region of hyperfine, high-frequency-shifted signals. The 1D spectra are also reported on the top of the NOESY maps. Signals marked by asterisks arise from protons of residues bound to the cobalt(II) or nickel(II) ions. Signal and cross peak labeling refer to the assignments summarized by Bertini et al.²⁰ Experimental conditions were: (a), lower map mixing time 4 ms, relaxation delay 80 ms, 256 experiments in F_1 and 512 experiment in F_2 ; upper map mixing time 15 ms, relaxation delay 150 ms (in order to better detect connectivities between hyperfine shifted signals and diamagnetic signals); (b), mixing time 15 ms, relaxation delay 80 ms, 512 experiments in F_1 and 1024 experiments in F_2 . The inset in (b) shows a region of a NOESY spectrum recorded under the same experimental conditions at 300 MHz. All the observed connectivities in $\text{Cu}_2\text{Co}_2\text{SOD}$ involve signals of copper-coordinated residues. In the NOESY map of $\text{Cu}_2\text{Ni}_2\text{SOD}$, connectivities 1–5 arise from intraresidue connectivities involving imidazole protons of residues bound either to Ni(II) (1) or Cu(II) (2–5). Connectivities 6 and 7 arise from interresidue contacts involving copper-coordinated histidines

It should be noted that the signals of the protons of the copper ligands are even sharper [due to the lower S value of copper(II) than of cobalt(II) and nickel(II)] than those of the cobalt or nickel ligands. All the metal–ligand proton signals, as well as several signals due to protons of residues located close to the two paramagnetic centers, have been firmly assigned through 1D NOE (see *Nuclear Overhauser Effect*) and/or 2D NOESY (see *NOESY* experiments). In Figure 3 the NOESY spectra of $\text{Cu}_2\text{Co}_2\text{SOD}$ and $\text{Cu}_2\text{Ni}_2\text{SOD}$ are reported.^{20,35,36} In these maps, besides many intraresidue connectivities, some inter-residue connectivities are also detected between the copper ligand protons. In $\text{Cu}_2\text{Ni}_2\text{SOD}$ some intraresidue connectivities have also been detected for nickel(II) ligand protons (see inset in Figure 3), while no connectivities between protons of residues coordinated to the cobalt(II) ion in $\text{Cu}_2\text{Co}_2\text{SOD}$ could be observed. The latter effect is due to the very short T_2 values of the signals which render the broad NOESY cross peaks expected in these cases difficult to detect.

The signals of the protons in the copper site are sharper in $\text{Cu}_2\text{Ni}_2\text{SOD}$ than in $\text{Cu}_2\text{Co}_2\text{SOD}$. This is the result of the shorter electron relaxation times of nickel(II) than of cobalt(II) in tetrahedral geometry. For the signals of the ligands of the zinc site, the spin state of Ni^{2+} , $S = 1$, makes the Curie contribution to their linewidth smaller than for those in the cobalt(II)-substituted derivative.

Cobalt(II) has also been used to replace the native copper(II) to obtain either $\text{Co}_2\text{Zn}_2\text{SOD}$ or $\text{Co}_2\text{Co}_2\text{SOD}$; the above derivatives have been investigated through NMR and the signals of the metal-coordinated residues have been observed even if no detailed assignment was attempted.²⁰

The ^1H NMR signals for metal–ligand protons have also been detected in $\text{Co}_2\text{Cu}_2\text{AP}$, for the ligands of copper ion,²² and in iron(II)–cobalt(II) uteroferrin³⁷ (see *Nonheme Iron Proteins*) for the ligands of the iron(II) ion. Indeed, the effect of the coupling is quite general. In all the proteins which contain two metal binding sites close enough that magnetic coupling can occur, NMR characterization of the metal sites can be successfully performed provided that one of the metal ions has short electron relaxation times.

Heteronuclear NMR spectroscopy has been rarely applied in the case of dimers. ^{15}N – ^1H HMQC spectra (see *Heteronuclear Shift Correlation Spectroscopy*) have been recorded on $\text{Cu}_2\text{Co}_2\text{SOD}$, detecting the ^{15}N – ^1H scalar couplings for the copper-bound histidines.³⁸ This is the first case in which ^{15}N – ^1H connectivities involving residues directly coordinated to the metal center of a paramagnetic protein have been observed.

7 CONCLUSIONS

Some of the examples discussed above clearly indicate that cobalt(II) substitution is *still* a powerful technique for the ^1H NMR spectroscopy of metalloproteins, although the actual capabilities of ‘standard’ multidimensional experiments are such that the 3D structure of proteins up to MW 30 000 can now be determined (see *Biological Macromolecules: Structure Determination in Solution, Structures of Larger Proteins, Protein-Ligand, and Protein-DNA Complexes by Multi-Dimensional Heteronuclear NMR*). In the case of proteins containing paramagnetic metal ions, which provide hyperfine-shifted signals which are

too broad, Co^{2+} and/or Ni^{2+} substitutions allow a good structural characterization of the protein region around the metal center. In the case of relatively small proteins, standard NMR experimental procedures for diamagnetic systems can be successfully combined with the analysis of 2D NOESY and COSY maps designed for the detection of connectivities between the hyperfine shifted signals to obtain the overall 3D protein structure in solution. Hence, the ‘paramagnetism’ of the system is no longer a drawback for the complete characterization and for the determination of the solution structure. In the case of large proteins such results cannot be achieved, but valuable local information on the active site can be obtained. Finally, we would like to stress the relevance of the evaluation of the χ tensor anisotropy and directions in cobalt(II)-substituted systems. Analysis of pseudocontact shifts, as formerly performed in the case of heme proteins, has also provided satisfactory results in cobalt(II)-substituted systems. More frequent utilization of such an approach is expected in the future.

1 INTRODUCTION

The presence of a 3d transition metal in their interior makes Cu proteins challenging and interesting subjects of study by NMR techniques. In addition, in a number of cases the properties of the protein matrix make them eminently suitable for the application of advanced NMR spectroscopic techniques, despite the occasional inconvenience caused by the presence of a redox-active metal.

Although copper itself is NMR-visible this property has hardly been used in the study of copper proteins.¹ The two naturally occurring stable copper isotopes (⁶³Cu and ⁶⁵Cu, natural abundances 69.2% and 30.8%) have nonzero spin ($I = \frac{3}{2}$ for both isotopes), but the accompanying nuclear quadrupole moment is large enough to cause considerable relaxation and line broadening, except for cases where the metal environment is highly symmetric and the electrical field gradient is consequently zero. For coordination compounds the latter may sometimes be the case, but protein environments are usually of low symmetry and Cu NMR spectroscopy, therefore, has been of little practical value in the study of Cu proteins.

Copper in proteins may occur in more than one redox state: Cu(I) or Cu(II). Copper(I) is diamagnetic and produces no problems in the measurement and interpretation of NMR spectra. However, the metal is easily oxidized and changes over to the (paramagnetic) Cu(II) state, which may cause complications from a spectroscopic point of view. The electronic spin–lattice relaxation of Cu(II) is too slow (relaxation times of 1–3 ns) for Cu to be useful as a shift reagent. Instead, resonances from nuclei close to the metal are broadened beyond detection. This is often a nuisance, but it can be used to advantage in kinetic experiments where the rate of electron transfer to and from the Cu is measured (vide infra). The broadening effect may also be used as an additional help in the assignment of some peaks in the NMR spectrum of the protein. The metal then serves as a relaxation probe.

Thus the presence of Cu may impart some experimental obstacles to high-resolution studies of Cu proteins. NMR spectroscopists have tried to circumvent these by replacing the Cu with paramagnetic shift probes such as Ni(II) and

Co(II), which have shorter electron spin relaxation times, or with diamagnetic redox-inactive metals such as Ag(I), Zn(II), Cd(II), and Hg(II).^{2–5} Some of the latter nuclei are directly accessible to NMR spectroscopy (¹⁰⁹Ag, ¹¹³Cd, ¹⁹⁹Hg).

Copper proteins have been distinguished on the basis of the structural and spectroscopic characteristics of their metal sites.^{6,7} Type-I sites contain a single copper ion covalently anchored to the protein by three metal–ligand bonds, two of them provided by histidines that act as N-donors, and one by a cysteine that coordinates to the Cu via its S- γ atom. The Cu is located almost in the plane of the three ligands. A fourth ligand, usually a methionine, sometimes a glutamine, occupies one of the axial positions, while in the azurins an additional main-chain carbonyl oxygen may coordinate weakly at the opposite axial position. Type-I sites invariably function in electron transfer.

Type-II sites also contain a single Cu atom, often coordinated in a square planar configuration by four nitrogen/oxygen donors and one or two axial ligands, one of which may be a water molecule or the substrate. They are found, for instance, in various oxidases, often in conjunction with an organic cofactor.

Type-III sites contain a Cu₂ dimer which is fixed within the protein framework by six histidines. They function in the transport of oxygen (hemocyanins) or the activation of oxygen in oxidase or oxygenase reactions (tyrosinase).

For a long time the copper sites in the blue oxidases like ascorbate oxidase and laccase were thought to be of a composite of type-I, -II, and -III sites. Crystal structure determination of ascorbate oxidase has made it clear that at least in this oxidase the Cu atoms occur in the form of a single type-I site plus a trimer of Cu atoms arranged in an equilateral triangle, which may be considered as a new type of site (type-IV).

Finally, recent work on cytochrome *a*,*a*₃ oxidase and nitrous oxide reductase has provided evidence for the occurrence of a new type of Cu₂ dimer in which the Cu atoms are possibly bridged by a cysteine.^{8,9}

Until very recently the size of most copper proteins precluded the study of their structure by means of high-resolution ¹H NMR techniques. Investigations were thus limited to studies of the metal site and its immediate surroundings, as in the case of proteins containing a type-I or a type-II Cu center. Only in the case of the so-called blue (type-I) copper proteins did the size of the proteins appear sufficiently small to allow extensive structural and mechanistic studies by high-resolution 2D and 3D NMR techniques. No elaborate NMR studies of proteins with type-III or type-IV sites seem to have been reported to date. Very recently the application of *rec*-DNA techniques has allowed the isolation of single domains of larger Cu-containing proteins, and the study of these domains by NMR techniques is presently being pursued by various groups.

In the following sections the progress achieved over the past two decades in the NMR study of Cu proteins is briefly reviewed.

2 BLUE COPPER PROTEINS

2.1 Introduction

The so-called small blue copper proteins (96–155 residues), which invariably contain a type-I Cu site, were described

for the first time at the end of the 1950s/beginning of the 1960s (for recent reviews see References 10 and 11).^{10,11} The following subclasses are distinguished at present: proteins involved in bacterial respiratory electron transport (azurin, pseudoazurin, amicyanin, rusticyanin, and auracyanin), photosynthetic plant and algal proteins (plastocyanin), and plant proteins with unknown function [either nonglycosylated: 'cucumber basic blue protein' (CBP) and plantacyanin; or glycosylated: stellacyanin, umecyanin, mavicyanin, and cucumber peeling cupredoxin (CPC)]. During the course of time it gradually transpired that their relatively small size (10–15 kDa), robustness under extremes of pH and temperature, ease of isolation and purification, and stability in solution at high concentrations made the blue copper proteins excellently suitable for detailed NMR investigations. Their attractiveness was further enhanced when the crystal structures of a number of them were solved at the end of the 1970s/beginning of the 1980s (plastocyanin,¹² azurin¹³). Later the structures of amicyanins (Amcs),^{14,15} CBP,¹⁶ and pseudoazurin were reported.^{17,18}

The presence inside the protein of a metal capable of occurring in two oxidation states, one of which is paramagnetic, further heightened the appetite of NMR spectroscopists towards applying the tricks of their trade in unraveling the effect of the metal on the appearance of the NMR spectra. Most of the NMR studies have been performed on the azurins (Azus) from *Pseudomonas aeruginosa* and *Alcaligenes denitrificans*,^{19,20} the plastocyanins (Pcs) from *Phaseolus vulgaris* (French bean),²¹ spinach and *Scenedesmus obliquus*,^{22,23} amicyanin (Amc) from *Thiobacillus versutus*,²⁴ and stellacyanin from *Rhus vernicifera*,²⁵ but brief reports have also been published of various other blue copper proteins.^{26–30} Finally, it has recently been shown that the small blue copper proteins yield fairly easily to the application of *rec*-DNA and site-directed mutagenesis techniques and this has added a new dimension to their study.¹¹ For instance, the application of multidimensional heteronuclear MR techniques on isotopically-enriched (¹³C and ¹⁵N) proteins has now become available.

2.2 Copper Site Structure

Some of the first investigators to study copper proteins by NMR techniques were Blumberg et al.,³¹ who around 1965 tried to assess the accessibility of the metal towards water molecules. They measured the relaxation enhancement of the bulk water protons as a function of the protein concentration and the oxidation state of the metal(s). In Pc, for instance, the Cu appeared inaccessible towards water. Application of this technique only required the study of the easily observable bulk water signal and not that of the protein. It would take 10 more years before spectrometers of sufficient resolution and sensitivity would become available to enable the successful tackling of the latter task. In the second half of the 1970s the first reports on the ¹H NMR spectra of various Pcs,^{32–35} of *P. aeruginosa* Azu,^{36–38} and of *R. vernicifera* stellacyanin appeared.³⁹ Also natural abundance ¹³C NMR studies of Azu and Pc were reported around this time.^{40,41} The spectra were much too complex to allow a detailed assignment of the signals, and attention primarily focused on the assignment by type of a few amino acids such as histidines and methionines, which give rise to easily identifiable singlet signals and (in the case of histidine) a characteristic pH titration behavior.

Since the four canonical ligands of a type-I Cu site comprise (apart from a cysteine) two histidines and a methionine, the structure of the Cu site in blue copper proteins rapidly became a popular subject of study by NMR techniques. By comparing the spectra of the Cu(II), Cu(I), apo-, and Hg(II)-substituted forms,³⁷ the ligands of the Cu could be identified correctly in Azu and Pc. Later on, these assignments were elaborated by 1D and 2D ¹H NMR and 2D ¹H{¹¹³Cd} and ¹H{¹³C} NMR studies.^{42–48} The ¹H NMR signals of the metal ligands could be shifted outside the envelope of the regular NMR spectrum by replacing the Cu by paramagnetic shift probes such as the 3d metal ions Co(II) and Ni(II).^{48,49} This essentially provided clearly resolved signals from protons in the first coordination shell of the metal, but the unraveling of the various contact and pseudocontact contributions to the paramagnetic shifts proved too complicated to make this subterfuge much use in the analysis of the behavior and structure of the Cu site.

An illustration of the difficulties of this approach is provided by the study of Dahlin et al.²⁵ who made an elaborate attempt to identify the Cu ligands in the plant blue copper protein stellacyanin. The nature and coordinating properties of the fourth Cu ligand in this protein had long been an enigma, since the lack of methionines in the amino acid sequence provided indelible proof that the metal-binding site in stellacyanin was at least different in one respect from that in the Azus and Pcs. Despite careful analysis, the NMR results obtained on the Co(II)-substituted form of stellacyanin remained ambiguous. Subsequently, structural research on the related 'cucumber blue protein',⁵⁰ and site-directed mutagenesis studies on Azus,⁵¹ have made it clear that the fourth ligand in stellacyanin is probably a glutamine.

The study of Ni(II) and Co(II)-substituted Azus has recently been taken up again by Moratal et al.^{52,53} who are applying multidimensional NMR techniques to study paramagnetically shifted signals. This work may provide further insight into the malleability of the metal site, as probed already by NMR and XRD (X-ray diffraction) studies of wild-type and mutant blue copper proteins in their apo and holo forms, or with Cd(II), Hg(II), or Zn(II) substituted at the metal site.^{10,11} The latter investigations have demonstrated that the metal site is preformed by the protein matrix, but does still retain some flexibility and is able to adapt somewhat to the metal that is substituted for the Cu.

Several attempts have been made to identify differences in structure and the Cu-binding mode of the metal sites between the Azus and the Pcs. Additional inspiration for this work came from XRD reports showing that the Cu site in Pc more closely resembled a distorted tetrahedron, while the coordination of the Cu in Azu was more like that of a trigonal bipyramid, with three strong almost in-plane ligands (two histidines and a cysteine) and two axial ligands, provided by a methionine sulfur (Met-121) and a backbone carbonyl oxygen (Gly-45).^{6,11} Differences in chemical shift of the ¹¹³Cd NMR signal of Cd-substituted Azu and Pc seemed diagnostic of a difference in electronic structure,^{54,55} but the difference was not easy to interpret. Further, the early ¹³C NMR studies of Azu implicated close proximity or possibly binding of a backbone carbonyl oxygen to the Cu.⁴⁰ Debate is still continuing regarding the amount of covalency involved in the Cu–S(Met) bond and the actual involvement of the Gly-45 carbonyl in determining the Cu-site properties in the Azus.

2.3 The Effects of pH

A clear difference between Pcs and Azus was provided by the pH titration behavior of the metal site. While the Cu site in the Azus is insensitive to pH, the geometry of the Cu site in the reduced form of the Pcs changes from fourfold to threefold towards low pH as one of the histidine ligands (His-87, *P. nigra* numbering) becomes protonated and dissociates from the Cu. This was beautifully documented by a series of XRD studies by Freeman et al.,⁵⁶ and confirmed later by ¹H NMR studies.^{42,57,58} A similar effect is seen to occur in the Amcs described for the first time in the early 1980s, i.e. the blue copper proteins that act as electron acceptors of methylamine dehydrogenases in C₁ organisms. Thus the Amc from *T. versutus* was studied in detail by NMR spectroscopy, and the dissociation of the histidine ligand at low pH (His-96, *T. versutus* numbering) was shown to occur in two steps with different timescales.⁵⁹ As the change in coordination with pH is seen only for the reduced and not for the oxidized form of the protein, electron transfer at low pH is accompanied by a large change in conformation around the Cu. It is not surprising, therefore, that a slowing down of the electron transfer as catalyzed by Amc or Pc is observed under acidic conditions.⁵⁹ A similar lability of the Cu site probably occurs in the pseudoazurins.⁶⁰ It appears, therefore, as what was initially considered an anomaly in the case of Pc (a pH-dependent Cu-site structure) relative to Azus, seems to be the rule for small blue copper proteins and that the pH-insensitive Cu site of the Azus constitutes the anomaly.

A pH effect of a different kind was observed for Azu from *P. aeruginosa*, and for a long time its precise nature and mechanistic relevance remained a source of speculation. Almost from the very beginning of the NMR studies on the Azus it appeared that Azu from *P. aeruginosa* is involved in a pH-dependent equilibrium between two conformations which on the NMR timescale are in slow exchange.^{37,46} From successive NMR studies it transpired that residue His-35 is responsible for this phenomenon and that the two conformations of the protein are related to the different states of protonation of His-35. Subsequent studies of the kinetics of the electron exchange between Azu and cytochrome C₅₅₁ seemed to necessitate the assumption that Azu may occur in two states, one redox-active and the other one redox-inactive, and that the equilibrium between them was pH-dependent. The pK_a of this transition appeared to be the same as that of His-35. Since in the crystal structure His-35 is in van der Waals contact with the Cu ligand His-46, the hypothesis was advanced that (one of) the electron transfer pathway(s) in Azu runs through His-35 and His-46, and that His-35 might act as a switch depending on the pH of the surrounding medium. This hypothesis was subsequently tested by a large number of groups.⁶¹

Eventually, a combination of (a) NMR studies of the electron self-exchange (ESE) reaction of wild-type Azu and of Azus with mutations at residue 35 and in the hydrophobic patch surrounding the other histidine ligand (His-117),^{62,63} (b) kinetic studies of the electron exchange between Azu mutants and physiological partners such as cytochrome C₅₅₁ and nitrite reductase,⁶⁴ and (c) XRD studies of wild-type and mutant Azus^{65,66} have led to the conclusion that His-35 is not in the electron transfer path to and from the Cu. Instead, Cu-ligand His-117, which pierces the protein surface at the position of

the hydrophobic patch, provides the sole port of exit and entry for the electrons. Small changes in the chemical shifts of the protons in the first and second coordination shell of the metal as a function of protonation state of His-35 reflect a 180° flip in the Pro-36/Gly-37 peptide bond which is at H-bonding distance of the N-δ of His-35. The position of His-35 relative to the Cu site is hardly affected. Finally, the redox activity of the protein appears to be independent of pH.

The only parameter relevant to the redox properties of the Azu affected by the change in protonation of His-35 is the midpoint potential which drops by 60 mV if His-35 is deprotonated.⁶³ It is interesting to note that in Pc a pathway running through Cu ligand His-87 (*P. nigra* numbering) similar to the His-117 pathway in the Azus has been delineated, but that here a second, albeit less efficient route for electron transfer has been identified starting at the 'eastern side' of the protein at the Tyr-83 residue.^{10,67,68}

2.4 Electron Transfer

The ESE rates of the blue copper proteins have attracted considerable attention apart from the metal site. It turned out that NMR methods are particularly suitable for the determination of these rates.^{3,69,70} Due to small conformational differences the NMR spectra of the oxidized and reduced forms of a blue copper protein show numerous small differences. In addition, in the paramagnetic [Cu(II)] species, the signals from nuclei close to the Cu are broadened beyond detection. In a solution containing a mixture of the reduced and oxidized form, exchange of an electron may occur when an oxidized and a reduced molecule collide. As a result two observations can be made. First, as the exchange becomes faster, signals from the same proton which occur at different positions in the spectra of the oxidized and reduced protein begin to merge. Secondly, signals that are only observed for the diamagnetic species may begin to broaden.

The first phenomenon may be adequately analyzed with customary 'chemical exchange' theory and information about the ESE rate can be obtained directly. The second phenomenon can be analyzed most readily in the so-called strong pulse or slow exchange limit. This limit applies if during the time the protein is in the paramagnetic state the nuclear spins are dephased to a sufficient extent that any phase coherence left over from the period the protein was diamagnetic is wiped out. Thus, effectively only the (lifetime broadened) signal deriving from the diamagnetic protein is observed and the broadening in (rad s⁻¹) is directly equal to the inverse lifetime of the diamagnetic state. For the paramagnetic dephasing to be strong enough, the nucleus whose signal is studied should be close enough to the copper. In practice, the strong pulse condition is met for nuclei which are located on side chains of the Cu ligands. When nuclei further away from the Cu are used for this technique erroneous results may be obtained, as is illustrated by a study of Azu where the ESE-induced broadening of the His-35 proton signals was used to determine an ESE rate which was two orders of magnitude off the correct value.^{71,72}

The high second order ESE rates ($8 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$) observed for the Azus have been interpreted as indicating that formation of the association complex is thermodynamically favorable.^{71,73,74} Current ideas are that the edges of the His-117 side chains in both Azus in the association complex

have to come sufficiently close for efficient electron transfer to occur, this being achieved when the two Azu molecules associate with their hydrophobic patches along each other. In the case of the Pcs a similar association complex has to be formed, but here the association is hampered by the presence of charged residues in or close to the hydrophobic ('northern') patch of the protein surface, which for most plant Pcs results in ESE rates of less than $1 \times 10^3 \text{ M}^{-1} \text{ s}^{-1}$.^{75,76} For the algal Pcs, which lack these charged residues in the hydrophobic patch, the ESE rates may reach values of $10^5 \text{ M}^{-1} \text{ s}^{-1}$.⁷⁰ For Amc, which in some respects resembles the algal Pcs, rates on the order of $1 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$ have been measured.⁵⁹ In line with these observations is that the ESE rates of the Azus are independent of ionic strength,⁷³ while those of the Pcs,⁷⁵ and to a smaller extent those of the Amcs,⁵⁹ increase when salts are added to the sample solution. Multivalent cations such as Mg(II) have appeared especially effective in promoting ESE.⁷⁵ Interestingly, redox-active compounds, such as ferricyanide, may catalyze the protein ESE reaction.^{35,77}

To identify areas on the protein surface where other electron transfer proteins might possibly associate, the complexation of blue copper proteins with redox-inert paramagnetic transition metal compounds serving as charged analogs of protein partners have been studied.^{22,57,58,78–80} By identifying and assigning the affected signals in the NMR spectrum, the location of the complex on the protein surface could sometimes be identified. In a similar way the association of blue copper proteins with proteins such as cytochrome *c* and cytochrome *f* have been studied directly. For this, the perturbation of the NMR spectrum of the blue copper protein that resulted from the admixture of the cytochrome and vice versa was investigated.^{81–83} The inhibition of protein/protein complex formation by transition metal complexes was also studied in this manner. For this method to be successful it is of importance to dispose of a complete assignment of the NMR spectrum of the protein under study. Such assignments are now available for a number of cases.

2.5 Structural Studies

Complete NMR assignments for blue copper proteins started to become available in the second half of the 1980s. Two-dimensional ^1H NMR assignment studies have been performed on the Pcs from spinach,²² *P. vulgaris* (French bean),^{84,85} and the alga *S. obliquus*.⁸⁶ The assignment of the ^1H NMR spectrum of Amc from *T. versutus* has also been accomplished using 2D NMR techniques.²⁴ Finally from the analysis of 2D and 3D homo- and heteronuclear NMR experiments, complete ^1H and ^{15}N NMR assignments have become available for the Azus from *P. aeruginosa*¹⁹ and *A. denitrificans*.²⁰ An interesting observation for the latter two proteins was that the differences in C- α -H chemical shifts did not average out to zero, contrary to the differences in amide proton chemical shifts. This is the subject of further study at the moment.

The secondary structures derived from the NMR results compared well with the published XRD structures in the case of the Pcs and Azus. For the Amc no XRD results were available initially, and the NMR results (later confirmed by more elaborate NMR studies and XRD investigations) showed an unusual extension of the N-terminus compared with the Pcs and Azus. Subsequent determination of the 3D

structures of the Pcs from *S. obliquus*²³ and *P. vulgaris*²¹ on the basis of the NMR results showed extensive similarity with the XRD-derived 3D structure of Pc from *P. nigra*. The NMR results formed a nice starting point for further structural investigations. Wright and coworkers studied the denaturation and refolding of Pc as well as the folding behavior of peptide fragments that were synthesized according to the natural amino acid sequence of the Pc. In this way a beginning could be made with the tentative delineation of the natural folding pathway(s) of Pc.^{87,88} The 3D structure in solution of Amc from *T. versutus* was determined by NMR methods at the same time that an XRD study could be completed.^{14,89} A detailed comparison of the two structures still has to be performed, but the overall structures do show a great deal of similarity.

3 NONBLUE COPPER PROTEINS

3.1 Superoxide Dismutase (SOD)

SOD is a eukaryotic homodimeric metalloenzyme (M_r approx. 30 kDa) which catalyzes the disproportionation of O_2^- to O_2 and H_2O_2 .⁹⁰ Each monomer contains a structural Zn(II) site and a catalytic type-II Cu(II) site. An imidazolate bridges the two metal ions which are about 6 Å apart. The metal ions in the native enzyme $\text{Cu(II)}_2\text{Zn(II)}_2\text{SOD}$ can be readily removed or substituted. The crystal structures of bovine and spinach $\text{Cu(II)}_2\text{Zn(II)}_2\text{SOD}$ ^{91,92} and of the $\text{Cu(II)}_2\text{Co(II)}_2$ derivative of bovine SOD⁹³ have been determined by X-ray crystallography. NMR experiments have been performed with bovine, human, and yeast SODs, which have similar catalytic, spectroscopic, and structural properties.

Because of their relatively large size, the assignment of all resonances in the ^1H NMR spectrum has not been achieved to date for any SOD. NMR experiments have been directed mainly at the study of the metal sites and their environment, including the interaction with exogenously added molecules like small anions and water. In the 1970s, work on SOD commenced by looking at the C- δ H and C- ϵ H resonances of His residues. The resonances of His ligands of the metal ions were tentatively identified by their broadening in the ^1H NMR spectrum of paramagnetic $\text{Cu(II)}_2\text{Zn(II)}_2\text{SOD}$ when compared with the spectrum of diamagnetic $\text{Cu(I)}_2\text{Zn(II)}_2\text{SOD}$,^{94–96} and by the reduction of their C- α ,H exchange rate.⁹⁷ His resonances were also investigated in the spectra of the diamagnetic forms $\text{E}_2\text{E}_2\text{SOD}$ (E denotes an empty metal site), $\text{E}_2\text{Zn(II)}_2\text{SOD}$, and $\text{Zn(II)}_2\text{Zn(II)}_2\text{SOD}$. It appears that the metal-site conformation is preserved among these derivatives.

A breakthrough in the study of the metal sites of SOD was achieved when Bertini et al. investigated the metal derivative $\text{Cu(II)}_2\text{Co(II)}_2\text{SOD}$ by NMR spectroscopy.^{90,98} Because of the magnetic coupling between Cu(II) and Co(II), which reduces the electron relaxation time of Cu(II), the resonances of protons near the Cu(II) ion are much less broadened than for $\text{Cu(II)}_2\text{Zn(II)}_2\text{SOD}$, and moreover experience large isotropic hyperfine shifts like the resonances of protons near the Co(II) ion. Similar observations have been made for $\text{Cu(II)}_2\text{Ni(II)}_2\text{SOD}$.⁹⁹ The metal-site ^1H resonances have been assigned, firstly by studying the effects of $^1\text{H}/^2\text{H}$ exchange on the 1D ^1H NMR spectrum and by analyzing 1D T_1 , T_2 and ^1H NOE measurements,^{90,99} and

secondly by the recent application of 2D ^1H NMR techniques (COSY, NOESY).^{2,100–102} Using $\text{Cu(II)}_2\text{Co(II)}_2\text{SOD}$ and $\text{Cu(I)}_2\text{Co(II)}_2\text{SOD}$, it was shown that the breakage of the imidazolate bridge between the metal ions upon reduction of the copper occurs at the Cu side,¹⁰³ a result that had already been anticipated on the basis of ^{113}Cd NMR spectroscopy of $\text{Cu(II)}_2\text{Cd(II)}_2\text{SOD}$ and $\text{Cu(I)}_2\text{Cd(II)}_2\text{SOD}$.¹⁰⁴ From NMR experiments involving both protons and nuclei such as ^{13}C , ^{19}F , ^{31}P , and ^{35}Cl on SOD metal derivatives and SOD with mutations in the substrate-binding cavity, valuable insights were obtained regarding the interaction of the protein with substrate-mimicking and other anionic compounds such as CN^- , N_3^- , NCO^- , NCS^- , F^- , Cl^- , H_2PO_4^- , and HCO_2^- .^{2,90,100,101,105–110} The accessibility of the Cu site in native and mutant $\text{Cu(II)}_2\text{Zn(II)}_2\text{SOD}$, and the effect of anion binding on it, has also been studied by measurements of the paramagnetic effect on the relaxation properties of solvent water.⁹⁰ The picture that arises from these studies is that some anions (in order of decreasing efficiency $\text{CN}^- > \text{N}_3^- > \text{NCO}^- > \text{NCS}^-$) bind to the Cu ion and displace a semicoordinated water molecule, thus reducing the solvent accessibility and affecting one of the Cu–His bonds. The effects of F^- and Cl^- binding are still smaller, making it questionable whether they bind to the Cu ion or to residues in its environment; phosphate and formate do not bind to the Cu ion but to residues near the copper. In addition to the Cu ion, one Arg and two Lys residues in the substrate-binding cavity have a particular effect in determining the affinity of SOD for anions.

3.2 Amine Oxidase (AO)

The eukaryotic copper-containing amine oxidases are dimeric metalloenzymes (M_r 170–190 kDa)¹¹¹ that have various functions, amongst others, in the metabolism of biogenic primary amines. Per dimer they contain two type-II Cu sites and one covalently bound organic cofactor with a quinone functionality. NMR studies of the protein have been confined to this cofactor and its orientation relative to the Cu site(s). ^1H NMR characterization of a small peptide from bovine serum AO that contained the phenylhydrazone-derivatized cofactor revealed it to be 6-hydroxydopa.¹¹² Using several fluorine-labeled phenylhydrazine derivatives, the distance between the organic cofactor at the amine-substrate-binding site of porcine plasma AO and one of its Cu(II) ions was inferred from the effect the paramagnetic Cu(II) exerts on the relaxation behavior of the fluorine nuclei as measured by ^{19}F NMR spectroscopy.¹¹³ The organic cofactor and the Cu(II) ion appear to be within approximately 9 Å from each other.

3.3 Copper-Storage, -Transport and -Resistance Proteins

Several proteins involved in the storage and delivery of Cu ions, as well as in protection against Cu overload, are known. NMR reports concerning the Cu-containing forms of these proteins are scarce. Two examples which have been studied by NMR spectroscopy may be mentioned. In yeast, a 53-residue metallothionein (MT) involved in Cu resistance binds copper as Cu(I). Complete sequential ^1H NMR assignments have been made for the Cu(I)-containing MT as well as for the Ag(I)-substituted form.¹¹⁴ The ligation pattern of the

metal ions was derived from heteronuclear $^1\text{H}\{^{109}\text{Ag}\}$ HMQC spectroscopy.^{114,115} It is noted that the 3D structures of several mammalian MTs have been determined with homo- and heteronuclear 2D NMR spectroscopy using the ^{112}Cd - or ^{113}Cd -substituted proteins.¹¹⁶

As a second example, the interaction of the high- M_r blood plasma protein albumin (67 kDa) with Cu(II), Co(II), and Ni(II) ions has been investigated by 1D and 2D ^1H NMR spectroscopy.^{117,118} It appeared to be possible to detect such interactions at the mobile N-terminus, for which relatively sharp resonances are observed in the ^1H NMR spectrum of the metal-free protein.¹¹⁹

3.4 Other Cu Proteins

A very limited number of NMR reports on other Cu proteins or related model compounds has appeared in the literature. Here we mention two NMR studies that are concerned with Cu sites that have not been dealt with so far in this review. First, crystalline bovine heart cytochrome *c* oxidase (M_r 200 kDa), that contains so-called Cu_A and Cu_B sites, has been studied by solid state ^{13}C NMR spectroscopy.¹²⁰ The spectral resolution appeared to be better than that of dissolved or lyophilised samples and to be comparable with that of crystals of the much smaller protein lysozyme, without severe interference from the paramagnetic metal ions. Measurements of T_1 indicated that the backbone of cytochrome *c* oxidase is more flexible than that of lysozyme. Second, it has been reported that a dicopper dioxygen model compound for the dinuclear type-III Cu site in high- M_r metalloproteins such as hemocyanin exhibits very normal looking ^1H and ^{13}C NMR spectra, indicating strong coupling between the Cu(II) ions.¹²¹

1 INTRODUCTION

Distance geometry is a general methodology which formulates conformational problems in terms of distance and chirality constraints.¹ It has been applied to such diverse problems as the conversion of two-dimensional chemical diagrams into three-dimensional structures, the systematic enumeration of all possible stereoisomers and conformers of small molecules, the docking of ligands to their receptors, and the construction of protein models by homology. It also plays a central role in present-day methods for determining the solution structures of proteins and other biological macromolecules from NMR data. There are several reasons for this. First, NMR spectroscopy, particularly the NOESY experiment, provides a wealth of data that are readily interpreted in terms of distance constraints. Second, although the problem of finding atomic coordinates consistent with distance constraints is a highly nonlinear one, unlike the problem of locating the global energy minimum it can nevertheless be solved quite reliably. Third, since the global minima of the functions that are minimized in distance geometry should have the value zero, the distance geometry formulation of the structure determination problem makes it relatively straightforward to find errors in the interpretation of the data.

2 GEOMETRIC REASONING WITH DISTANCE INFORMATION

Newcomers to distance geometry should be careful not to confuse it with the least-squares fits that are widely used in crystallography. Instead of seeking a *single* ‘best fit’ to the data as in the least-squares method, the goal of distance geometry is to understand better the set of all conformations consistent with the data as a whole. This is done by deriving new geometric facts about the molecule from those that are available experimentally, in a process known more generally as *geometric reasoning*. There are several ways of going about this, as described below.

2.1 Describing Molecular Conformation

A *distance geometry description* defines the set of possible conformations of a nonrigid molecule by means of lower and upper bounds on its interatomic distances, together with the chiralities of its rigid tetrahedra of atoms. The set of conformations consistent with these constraints itself is called *conformation space*. Such a description is usually not chemically complete, meaning that there may be conformations in the space that do not exist in appreciable concentration under the conditions of interest. It may also contain noncritical constraints, i.e. constraints that could be tightened without reducing the conformation space consistent with them, or it may contain redundant constraints, i.e. constraints that could be loosened or eliminated without enlarging the space.

The distance constraints may come from many sources. Clearly, the molecular formula (bond arrangement) is one of them, since both covalent bond lengths as well as the geminal distances which define the bond angles are determined essentially exactly by this information. Many other distances can also be fixed within larger rigid groups of atoms, e.g. aromatic ring systems. In addition, the distance between all pairs of atoms separated by four or more bonds may be assumed to be at least the sum of suitable hard sphere atomic radii, and other noncovalent interactions, e.g. hydrogen bonds, can also be modeled by means of distance constraints. Finally, distance constraints are available from many kinds of experiment, including optical fluorescence transfer, various noncrystallographic diffraction experiments and, of course, NMR spectroscopy. As a general rule, one should collect as many constraints as possible, since even redundant constraints are useful in distance geometry calculations.

The most obvious case in which chirality constraints are needed is at asymmetric carbon atoms, since the distances between their neighboring atoms cannot be used to distinguish enantiomers. It turns out that chirality constraints are also useful in many other cases. For example, prochiral centers should usually be constrained in distance geometry calculations, against the possibility that stereospecific assignments may be available, and chirality constraints among α -carbon atoms can be used to enforce the handedness of α -helices. Planarity can also be viewed as a sort of chirality constraint (neither left- nor right-handed), which is applicable to most double bonds. Finally, although the absolute value of a torsion angle about the 2,3-bond in a chain of four atoms can be determined by specifying the 1,4-distance, its sign can only be fixed by also constraining the chirality of the tetrahedron the vertices of which are these four atoms.

In solution, by far the richest source of distance constraints is the two-dimensional NMR experiment NOESY. Since the nuclear Overhauser effect (NOE) that this experiment measures is due to dipole–dipole interactions, the intensity of a cross peak in a NOESY spectrum is roughly proportional to the average inverse sixth power of the distance between a pair of protons in the molecule. This means that (provided a short enough mixing time is used to eliminate the possibility of indirect NOEs) the mere presence of such a cross peak implies that the maximum distance between the protons is quite small, 0.50 nm at the most. Because the NOE is also proportional to a factor that depends on the unknown average

rate at which the interproton vector reorients (and may, in addition, be influenced by many other sources of relaxation), a more quantitative interpretation of the cross-peak intensities is difficult. Fortunately, as discussed in the last section of this article, in the important special case of globular proteins a reasonably precise and well-defined structure can often be obtained without quantifying most of the NOESY cross-peak intensities.

2.2 Inconsistent Distance Constraints

The task of collecting, processing, and interpreting NMR data, particularly on large molecules such as proteins in solution, is a complex one which is susceptible to many sources of systematic as well as random error. The distance geometry approach attempts to distinguish between these two types of error by interpreting the data geometrically in terms of constraints that are intended to encompass the *full range* consistent with the intrinsic uncertainty of the measurements due to thermal noise, intramolecular motion, and similar phenomena. Assuming (as is often the case) that the data are sufficiently complete and precise to determine a nearly unique conformation, any serious errors in the interpretation of some of the data will usually cause the constraints as a whole to become mutually *inconsistent*. This means that it is impossible to satisfy the constraints by any single conformation, which in turn implies that one or more of the assumptions made in interpreting the data must be false. Although the inconsistencies can be arbitrarily complex, in most cases it is possible to isolate them to relatively small subsets of atoms, meaning that the constraints among those atoms are by themselves inconsistent with any three-dimensional structure.

Any method of detecting inconsistencies in the constraints also makes it possible to falsify structural hypotheses, and thereby opens up one possible route towards geometric reasoning. Certain relatively simple ‘patterns’ of inconsistent constraints can not only be detected, but also isolated, by a process known as ‘bound smoothing’ (see below). More often, however, inconsistency can only be detected by repeatedly trying to calculate a conformation consistent with the constraints, and failing. Since the currently available algorithms for doing this are quite reliable, this situation strongly implies that the constraints are inconsistent. Unfortunately, the minimization procedures commonly used to calculate conformations result in a compromise between violations of the correct as well as the incorrect constraints, which makes it relatively difficult to isolate inconsistency by this approach, although there is a significant correlation between the frequency and severity of constraint violations and the correctness of the constraints.

2.3 Bound Smoothing and Distance Limits

An important class of distance geometry algorithms are designed to perform *bound smoothing*. These play a central role in the so-called EMBED algorithm (see Section 3.4), but the distance limits that bound smoothing algorithms compute are of much broader interest, and hence are described here. A more complete description, together with a detailed presentation of the algorithms themselves, is available.¹

The three-dimensional *distance limits* associated with any set of distance bounds are simply the minimum and maximum value that each distance can assume in any spatial structure the other distances of which all lie within their given bounds. Since the distance bounds available from NMR spectroscopy are necessarily imprecise and very sparse, computing the corresponding distance limits can reveal a great many consequences of the NMR data that are not obvious from direct inspection, thus providing another approach to geometric reasoning. The distance limits also enable one to detect redundant and critical distance constraints, since by definition the distance limits for redundant bounds are tighter than those bounds, while the distance limits for critical bounds are looser. Finally, the distance bounds as a whole are inconsistent if and only if the limits implied by the bounds among some subset of atoms violate the bounds, i.e. a lower bound exceeds its upper limit, or vice versa.

Unfortunately, the computation of the true three-dimensional distance limits is a difficult and unsolved problem, and only loose approximations are readily available. These are the limits implied by the bounds among subsets of three or four atoms at a time, which are known as the *triangle inequality* and *tetrahedron inequality limits*, respectively (Figure 1). These can be computed in time proportional to at most the cube, and at least the fourth power, of the number of atoms, respectively. Although much weaker than the true three-dimensional limits, particularly with regard to the lower limits, they are capable of revealing considerable redundancy in many sets of distance constraints, and they often succeed in catching typographical errors committed during data entry that otherwise could be located only after careful proofreading or long calculation.

Figure 1 Schematic drawing of the triangle (top) and tetrahedron (middle and bottom) limits; the upper limits are shown on the left half and the lower limits on the right. In these diagrams, solid lines indicate distances at their lower bounds, thick dotted lines indicate distances at their upper bounds, and thin dotted lines indicate the limit determined by this combination of bounds. Thus, for example, the upper left diagram indicates that the upper triangle inequality limit on the distance between the endpoints is obtained when the two distances to the midpoint are stretched to their upper bounds. The complete set of triangle or tetrahedron limits may be obtained by iteratively replacing the bounds by the corresponding limits whenever these are tighter, until no further changes occur

Figure 2 The triangle inequality limits among the α -carbon atoms of the 58 residue protein BPTI (above the diagonal), together with the distance matrix obtained from its crystal structure (below the diagonal). The rows and columns of this combined matrix are ordered in the same way as the corresponding residues in the BPTI sequence, and the cells are shaded according to the value of the corresponding limit or distance. The correlation between the upper limits and the distances is obvious

Another important use of the triangle (or tetrahedron) limits is as a means of predicting various structural features prior actually to calculating any structures. Although this can, in principle, be done with any sort of molecule, we shall concentrate here on the important case of globular proteins subject to NOESY distance constraints. Contoured plots of the distances among the α -carbon atoms have long been used as a visual aid to recognizing the secondary structure 'topology' of globular proteins. Moreover, there exists a strong positive correlation between the upper triangle limits and the actual distances (even when only a few NOESY constraints per residue are available).² Therefore, contoured plots of the upper limits can serve much the same purpose as distance matrices, and it is possible to determine the chain fold and other basic features of a protein from NMR data at a very early stage in the analysis. This in turn should facilitate that analysis. Figure 2 shows an example of such a contour plot for the protein basic pancreatic trypsin inhibitor (BPTI), along with its distance matrix.

2.4 The Ensemble Approach

Bound smoothing constitutes an example of *deductive* geometric reasoning. Another, in some ways even more important approach may be called *inductive* geometric reasoning. Here, one computes an *ensemble* of conformations which satisfy the constraints, but are otherwise 'random'. Then, provided that this conformational ensemble is sufficiently large (meaning, for most purposes, 10 to 20 conformations), any geometric features that are uniformly present in all its members may safely be assumed to be necessary consequences of the constraints. The geometric features of interest are not limited to distances,

but may include angles, chiralities, and far more subtle things such as the radius of gyration, surface accessibility or chain 'topology'. They may also include properties of the ensemble as a whole, such as the average or maximum 'difference' between any two conformations.

In structure determination by NMR spectroscopy, the most widely used measure of the difference between two conformations is the root mean square coordinate deviation (RMSD). This is simply the root mean square difference in their coordinate vectors (or equivalently, the root mean square distance between corresponding pairs of atoms) minimized over all translations and rotations of one conformation with respect to the other. This quantity may be computed among all the atoms, or among any desired subset (e.g. the α -carbons atoms of a protein). The average of the RMSD over all pairs of conformations in the ensemble is often used as a measure of the overall precision of an NMR structure determination, with 0.10 nm generally regarded as good, 0.20 nm as fair and 0.30 nm or more as poor. One should nevertheless be careful not to read too much into this single number. It is far more important to determine exactly how the conformations in the ensemble differ from one another than it is to determine by how much they differ on average. Fortunately, the translation and rotation which gives the RMSD also allows one to

Figure 3 Stereoview of an ensemble of 25 BPTI conformations computed from a set of simulated NMR distance constraints using the program DGII.⁴ These conformations (thin gray lines) have been superimposed on the crystal structure from which the constraints were derived (heavy black line) so as to minimize the RMSD to its α -carbon atoms, for an average RMSD of 0.085 nm

superimpose the structures so as to visualize easily their detailed differences by computer graphics (Figure 3).

Another commonly studied geometric feature is the torsion angles about single bonds. The precision of such cyclic parameters is best quantitated by means of an average value and ‘order parameter’, which is defined as follows. Given a single bond in the molecule, one puts a unit vector down in the plane for each conformation in the ensemble, whose angle with the x axis is equal to the value of the corresponding torsion angle in that conformation. On summing these unit vectors and dividing by the size of the ensemble, one obtains an average vector whose angle with the x axis is the average of the torsion angle, and whose length is the corresponding order parameter. This angular order parameter is unity only if the angle has exactly the same value in all conformations, and approaches zero as the angle becomes random.

3 DISTANCE GEOMETRY ALGORITHMS

Here the term ‘distance geometry algorithm’ is used somewhat loosely for any procedure that helps us to perform computer-aided geometric reasoning with distance and chirality constraints (including torsion angle constraints). Because of their utility in NMR studies of solution conformation, we concentrate here on algorithms for computing conformational ensembles. Several, rather different approaches have been taken to this problem, each of which has its advantages and disadvantages, but all of which have been successfully applied to large molecules. Rather than attempting an exhaustive survey, the discussion is limited to those algorithms which have been most widely used by NMR spectroscopists to date, or which appear particularly promising.

3.1 Restraints and Error Functions

A common feature of all these algorithms is that they rely on minimization of an error function, which measures the violations of the constraints.^{1,3,4} As such, an error function is always non-negative, and zero if, and only if, all the constraints are fully satisfied. The construction of an error function involves translating the constraints into *restraints*, that is, into functions of a single geometric parameter that force that parameter to satisfy its constraint when they are minimized. The error function is then obtained as the sum over all restraints.

A simple example of such a function is

$$E(\mathbf{p}_1, \dots, \mathbf{p}_N) = \sum \left[\max \left(0, \frac{d_{ij}^2}{u_{ij}^2} - 1 \right) \right]^2 + \sum \left[\max \left(0, 1 - \frac{d_{ij}^2}{l_{ij}^2} \right) \right]^2 + \sum C_{ijkl}^2(\mathbf{p}_1, \dots, \mathbf{p}_N) \quad (1)$$

where u_{ij} and l_{ij} denote the upper and lower distance bounds, and $C_{ijkl}^2(\mathbf{p}_1, \dots, \mathbf{p}_N)$ is a chirality restraint, which is described below. Squaring the distance restraints ensures that the

function has continuous first derivatives, as required by many minimization algorithms, while scaling them by the inverse-squared bounds ensures that the various restraints receive roughly equal weight, which tends to make minimization of the error function somewhat easier. Ideally, however, the results should be independent of the assumed weights.

The chirality restraints, which are ordinarily needed only when Cartesian coordinates are used as the variables (see below), are usually defined as

$$C_{ijkl}^2(\mathbf{p}_1, \dots, \mathbf{p}_N) = [\text{vol}(\mathbf{p}_i, \mathbf{p}_j, \mathbf{p}_k, \mathbf{p}_l) - v_{ijkl}]^2 \quad (2)$$

Here

$$\text{vol}(\mathbf{p}_i, \mathbf{p}_j, \mathbf{p}_k, \mathbf{p}_l) = (\mathbf{p}_i - \mathbf{p}_l) \cdot [(\mathbf{p}_j - \mathbf{p}_l) \times (\mathbf{p}_k - \mathbf{p}_l)] \quad (3)$$

is the oriented volume of the four atoms whose Cartesian coordinates are $\{\mathbf{p}_i, \mathbf{p}_j, \mathbf{p}_k, \mathbf{p}_l\}$, and v_{ijkl} is its target value. The well-known properties of the vector triple product imply that the oriented volume has absolute value equal to six times the volume of the tetrahedron spanned by the four atoms, and that its sign is positive for one chirality of this tetrahedron, negative for its mirror image, and zero whenever the atoms are coplanar.

There are two distinct ways of parameterizing the space of atomic configurations over which the minimizations must be carried out. The first uses three independent Cartesian coordinates for each atom, while the second uses the torsion angles about single bonds as the variables. The latter has the advantage of reducing the number of variables by about a factor of 10, which greatly improves the performance of many minimization algorithms. It also enables one to impose torsion angle constraints simply and directly, and maintains the covalent geometry automatically without the use of constraints on the bonded and geminal distances. As a consequence, however, it is not possible to correct violations of these constraints, which limits the methods that can be used to derive good starting structures for the minimizations. In addition, torsion angle optimizations are relatively complicated to implement, particularly if flexible rings are present in the molecules of interest. Both parameterizations are widely used in computational chemistry.

3.2 The Variable Target Function Algorithm

The variable target function algorithm was developed by Braun and Gö⁵ specifically for the purpose of computing the structures of proteins using distance constraints derived from NMR spectroscopy. By repeating the calculation many times, each time starting from a different set of randomly chosen torsion angles, one obtains the desired conformational ensemble. The method has been under continuous development since its introduction, and has become an effective tool for determining protein structures using distance and torsion angle constraints derived from NMR data. A survey of the early structures solved by this method is available.⁶

3.2.1 Avoiding Local Minima by Variable Target Functions

Even though torsion-based optimizations are quite efficient at converging to local minima, when used to solve distance geometry problems it is essential to find a global minimum of the error function. With large molecules such as proteins, the number of local minima is so large that this is highly unlikely to be achieved in any given run starting from a random conformation. The essential idea behind the variable target function approach is to avoid becoming trapped in local minima by initially minimizing a target (i.e. error!) function that restrains only the torsion angles together with the ‘short-range’ distances between neighboring amino acid residues, and gradually adding on longer and longer range restraints. In this way the ‘short-range’ or secondary structure is formed first, after which the secondary structural elements are docked together to form the tertiary structure, in a fashion that is analogous to the way in which proteins are widely believed to fold in solution. Although this heuristic method does not guarantee that a global minimum will be attained in any given run, it does increase the convergence ratio enough essentially to ensure that, with a little persistence, a global minimum with zero error will be found if one exists.

Because they require memory that grows only linearly with the size of the molecule, first-derivative based minimization methods such as conjugate gradients are generally used with the variable target function algorithm. The number of minimization iterations performed at each stage (restraint range) must be determined largely by trial and error, but does not seem to vary greatly from one protein to another. As a rule, it has been found more efficient to increase the range of the upper distance restraints obtained from NMR more rapidly than the lower distance restraints obtained as the sum of the hard-sphere radii (or, roughly equivalently, to weight the NMR restraints more strongly than the hard-sphere restraints in the initial stages), probably because the NMR restraints are far more effective at determining the tertiary structure than are the hard-sphere restraints. The method is particularly effective at determining the structures of proteins whose secondary structure consists primarily of α -helices, where the convergence ratio may approach 100%. With β -sheets or irregular structures, the convergence ratio can drop below 10%. This effectively lowers the efficiency of the method by a factor of 10, since nonconverging structures must be discarded and the minimization repeated until the desired number of conformations has been obtained.

3.2.2 Further Improvements in Speed and Reliability

The time required for each function/gradient evaluation is generally dominated by the time required to find all the hard-sphere overlaps, especially in the final stages of the variable target function algorithm when most of the hard-sphere restraints are considered. This can be greatly alleviated by using either grid-based or list-based methods to avoid checking most pairs of atoms for overlap. The hard-sphere overlap check, as well as much of the rest of the algorithm, has also been efficiently vectorized, so that each run can be performed very rapidly on a supercomputer.⁷ The convergence ratio can be improved by choosing the torsion angles of the starting structure for the minimization from within their allowed ranges, rather than completely at random. These ranges can

be reduced, and stereospecific assignments elucidated, by grid search methods which find those combinations of angles in each single residue that are consistent with the intraresidue distance constraints.⁸ More recently, it has been suggested that the throughput can be greatly improved by imposing the ranges of angles observed in converged segments of nonconverged structures as constraints in subsequent calculations.⁹ Finally, a minimization procedure has been proposed which, though apparently less efficient than conjugate gradients, yields error bounds on the torsion angles in the final conformations.¹⁰

3.3 Simulated Annealing and Related Methods

A second class of methods rely on a very general approach to global optimization problems known as simulated annealing. In this case, one treats the error function as an energy function, and uses either molecular dynamics or other methods to sample conformations with a Boltzmann distribution at a given absolute temperature. By slowly lowering the temperature, the distribution gradually narrows into a single energy minimum, and as in crystallization and similar physical processes this minimum will often be a global minimum. Because of the numerous error function calculations required, many of the above-mentioned methods of accelerating these calculations are also used in simulated annealing.

3.3.1 Dynamical Simulated Annealing

One way to generate conformations with a Boltzmann distribution is via molecular dynamics. This is a general method for simulating the evolution of molecular systems under the influence of a classical Hamiltonian $\mathcal{H}$, by iteratively solving Newton’s equations of motion:

$$m_i \frac{d^2 \mathbf{p}_i}{dt^2} = -\nabla \mathcal{H} \quad (4)$$

This may be done by using either the ‘leap-frog’ algorithm

$$v_i[(2k+1)\Delta t/2] = v_i[(2k-1)\Delta t/2] - \Delta t \frac{\nabla \mathcal{H}}{m_i} \quad (5a)$$

$$\mathbf{p}_i[(k+1)\Delta t] = \mathbf{p}_i(k\Delta t) + \Delta t v_i[(2k+1)\Delta t/2] \quad (5b)$$

or the Verlet algorithm

$$\mathbf{p}_i[(k+1)\Delta t] = 2\mathbf{p}_i(k\Delta t) + \mathbf{p}_i[(k-1)\Delta t] - (\Delta t)^2 \frac{\nabla \mathcal{H}}{m_i} \quad (6)$$

In the first applications of this method to NMR structure determination problems,^{11,12} the error due to the NMR restraints was added to an empirical energy function, and the combined function treated as the Hamiltonian of the system. This had several disadvantages. First, the strong forces between bonded and overlapping atoms necessitated the use of a small time step, which in turn meant that a large number of function and gradient evaluations were needed to reach equilibrium at any given temperature. Second, the function and gradient evaluations themselves required a relatively large quantity of computer time, because the forces involved in

empirical energy functions are relatively long range. Third, careful weighting of the NMR restraints was necessary in order to keep them from ‘drowning out’ the energy, or vice versa.

Despite these problems, by changing the weights of the short- and long-range restraints versus the energy as the annealing proceeded in a fashion similar to that used in the variable target function algorithm, impressive results were attained, including the folding of small proteins starting from a completely random array of atoms.¹³ Subsequently, it was found that the efficiency and reliability of the calculations could be further improved by dropping the energy entirely, and treating a simple error function as the Hamiltonian.^{14,15} In fact, in most cases the energy has little effect on the spread of the resulting conformational ensembles as measured by the average RMSD,¹⁶ although it does tend to sharpen the distribution of the torsion angles noticeably. As a rule, however, this can be achieved more efficiently by energy minimization once the overall structure has been determined.¹⁷

Although in actual attempts to simulate the physical evolution of chemical systems it is essential to keep the time step small enough to accurately conserve the energy of the system, when molecular dynamics is used as a heuristic for simulated annealing we have found it advantageous to use the largest possible time step consistent with numerical stability.⁴ A further improvement in efficiency can be attained by using the same mass for all the atoms, since numerical stability prevents the time step from being made much longer than the inverse rate of the fastest bond vibration. The temperature of the system can be controlled by rescaling the velocities, or by simulating a temperature bath via a temperature dependent viscosity term. Annealing has also been achieved by slowly making all the force constants larger, until the system becomes essentially rigid at a fixed temperature. While molecular dynamics can be performed using the torsion angles as the variables, such simulations are relatively uncommon and have only recently been applied to NMR structure determination problems. Further information on dynamical simulated annealing, and its applications to both NMR and crystallographic structure determination, may be found in recent reviews.¹⁸

3.3.2 Other Stochastic Optimization Methods

The classical method of generating atomic configurations with a Boltzmann distribution, known as the *Monte Carlo method*,¹⁹ dates back to the earliest days of scientific computing. This method does not use gradient information, and is applicable to either Cartesian coordinates, torsion angles, or even to discrete (combinatorial) optimization problems.²⁰ While several applications of Monte Carlo based simulated annealing to energy minimization have been reported, only one application to NMR structure determination has been published to date.²¹ The reason is that the usual implementations appear to be substantially less efficient than the dynamical simulated annealing method described above. The efficiency and reliability of the Monte Carlo method, however, hinges critically on the rate at which the temperature is lowered and the way in which the positions of the atoms are perturbed in each iteration. Recently, a variety of sophisticated methods have been developed for energy minimization purposes, which generate larger changes with a better chance of being accepted.^{22–24} It therefore seems likely that a Monte

Carlo procedure could be devised that performs reasonably efficiently with distance geometry problems.

Another class of stochastic minimization methods that appear suitable for distance geometry problems are known as *genetic algorithms*. Unlike the methods described above, which are based on a physical analogy, genetic algorithms are based on an analogy with the optimization of the ‘fitness’ of populations by natural selection. These methods have actually been available for some years,²⁵ but have only recently begun to attract widespread interest.²⁶ Once again, the basic procedure is simple, but the efficiency and reliability depend critically on how the basic steps are implemented. Using torsion angles as the variables, these procedures have recently been successfully applied to energy minimization problems,²⁷ as well as at least one distance geometry problem involving NMR data.²⁸ Genetic algorithms have the attractive feature of intrinsically computing ensembles of conformations, and hence, if reasonably good ways of implementing the basic steps can be found, they may prove to be an improvement over other torsion angle based algorithms.

3.4 The EMBED Algorithm and its Variations

The EMBED algorithm is a method of randomly generating the Cartesian coordinates of structures that roughly fit the distance constraints, and hence are good starting points for minimization by any method that is applicable to Cartesian coordinates. It was actually developed^{3,29} prior to the development of two-dimensional NMR, as part of a larger effort to demonstrate the applicability of distance geometry to a wide variety of experimental and theoretical information.³⁰ Shortly thereafter, it was employed to determine the conformation of fragments of micelle-bound glucagon from NMR data,³¹ and then to determine the first protein solution structure ever solved by NMR.¹⁷ It has since been used in the determination of more protein, DNA, and other biomolecular structures than the space available here permits us to present.

Structure calculations with the EMBED algorithm consist of three basic steps:

1. Using bound smoothing algorithms to estimate the best possible limits on the distances from the sparse and imprecise set of distance bounds given as input.
2. Guessing a random set of distances from within the limits, and computing Cartesian coordinates such that the distances calculated from these coordinates are a best fit to this guess.
3. Optimizing these coordinates by minimization of an error function so that both the distance and chirality constraints are satisfied.

By repeating steps (2) and (3) with different random number seeds in step (2), one obtains the desired conformational ensemble. Although all three steps have traditionally been considered to be part of the EMBED algorithm, steps (1) and (3) are of independent interest (as described above). For this reason we prefer to restrict our usage of the term to step (2). Since any method for minimizing error functions with respect to Cartesian coordinates can be used in step (3), the EMBED algorithm should be understood as being complementary to these methods, rather than a substitute for them. Indeed, the combination of the EMBED algorithm with simulated annealing is presently one of the most efficient and reliable methods available for NMR structure determination.^{4,32}

3.4.1 Random Distance Matrices by Metrization

Early implementations of the EMBED algorithm generated their random distance matrices by choosing the trial distances $[\tilde{d}_{ij}]$ independently of one another with a uniform distribution from within their limits. It was subsequently found that, when the density of distance constraints was quite low, the coordinates obtained in this way were uniformly expanded compared with those obtained by other methods. This undesirable tendency is eliminated by *metrization*, an extension of triangle inequality bound smoothing that enables one to choose random distance matrices which obey the triangle inequality from within the triangle inequality limits.^{33,34} In principle, by making the trial distances more realistic, this should also improve the quality of the embedded coordinates.

Metrization itself is based on a characterization of the triangle inequality limits which shows that if any distance is set to any value between its triangle inequality limits, values exist for the remaining distances so that all the distances satisfy both the triangle inequality and the limits. Thus by alternately setting one distance to some random value between its limits, then setting the corresponding lower and upper bounds to that distance and updating the limits by this change, one will eventually obtain a complete distance matrix satisfying both the triangle inequality and the limits. Provided that one uses a data structure known as a ‘shortest-paths tree’ to store the limits involving one atom, these updates can be accomplished in time proportional to the number of atoms, so that the overall time required is proportional to its cube.

Because triangle bound smoothing is more effective at lowering upper bounds than it is at raising lower bounds, it is necessary to randomize the order in which the atoms are considered for each metrization, in order to avoid having some parts of the structure come out systematically more compact than others. In applications to distance constraints derived from NMR data, it is also desirable to control the distribution with which the distances are selected so as to obtain average values that asymptotically tend towards some fixed fraction of the upper limits, since this ensures a correlation between the distances and the upper limits similar to that observed in practice (see Figure 2).

3.4.2 Embedding Distance Matrices

The trial distances chosen randomly from within the distance limits in the previous step are essentially always inconsistent, and hence cannot be realized by any possible conformation of the molecule. Nevertheless, if we can find coordinates that are a ‘best fit’ to these distances, then since the distances satisfy the constraints, the coordinates ought to at least come close. It turns out that a certain type of best fit can be rapidly calculated by eigenvalue methods.

To see how this works, suppose we are given a matrix of squared distances among a set of $N + 1$ points $\mathbf{p}_0, \dots, \mathbf{p}_N$, in three-dimensional space:

$$\mathbf{D} = [d_{ij}^2] = [\|\mathbf{p}_i - \mathbf{p}_j\|^2] \quad (7)$$

The symmetric, $N \times N$ matrix of dot products of the vectors from the zeroth point to all the rest is usually called the *metric*

or *Gram matrix* $\mathbf{G}$, and can be calculated directly from $\mathbf{D}$ via the well-known law of cosines:

$$\mathbf{G} = [(\mathbf{p}_i - \mathbf{p}_0) \cdot (\mathbf{p}_j - \mathbf{p}_0)] = \frac{1}{2}[d_{0i}^2 + d_{0j}^2 - d_{ij}^2] \quad (8)$$

Let $\mathbf{G} = \mathbf{U}\mathbf{\Lambda}\mathbf{U}^T$ denote the eigenvalue decomposition of $\mathbf{G}$, where $\mathbf{U}$ is the orthogonal matrix whose columns are the eigenvectors of $\mathbf{G}$ and $\mathbf{\Lambda} = \text{diag}(\lambda_1, \dots, \lambda_N)$ is a diagonal matrix containing its real eigenvalues sorted by decreasing value. Since $\mathbf{G} = \mathbf{P}^T\mathbf{P}$, where $\mathbf{P} = [\mathbf{p}_1 - \mathbf{p}_0, \dots, \mathbf{p}_N - \mathbf{p}_0]$ is a $3 \times N$ matrix, the matrix $\mathbf{G}$ is positive semidefinite of rank at most 3, so that $\lambda_1 \geq \lambda_2 \geq \lambda_3 \geq 0$ and $\lambda_4, \dots, \lambda_N = 0$. Thus if we define the 3×3 diagonal matrix $\mathbf{\Lambda}_3^{1/2} = \text{diag}(\lambda_1^{1/2}, \lambda_2^{1/2}, \lambda_3^{1/2})$ together with the $3 \times N$ matrix:

$$\mathbf{Q} = [\mathbf{q}_1, \dots, \mathbf{q}_N] = \mathbf{\Lambda}_3^{1/2}[\mathbf{u}_1, \mathbf{u}_2, \mathbf{u}_3]^T = \mathbf{\Lambda}_3^{1/2}\mathbf{U}_3^T \quad (9)$$

it follows that the points $\mathbf{q}_0 = 0$ and $\mathbf{q}_1, \dots, \mathbf{q}_N$ have the same Gram matrix as $\mathbf{p}_0, \dots, \mathbf{p}_N$:

$$\begin{aligned} \mathbf{G} &= (\mathbf{U}_3\mathbf{\Lambda}_3^{1/2})(\mathbf{\Lambda}_3^{1/2}\mathbf{U}_3^T) = \mathbf{Q}^T\mathbf{Q} = [\mathbf{q}_i \cdot \mathbf{q}_j] \\ &= [(\mathbf{q}_i - \mathbf{q}_0) \cdot (\mathbf{q}_j - \mathbf{q}_0)] \end{aligned} \quad (10)$$

They also have the same distance matrix, since $\|\mathbf{p}_i - \mathbf{p}_0\|^2 = g_{ii} = \|\mathbf{q}_i - \mathbf{q}_0\|^2$ for $i = 1, \dots, N$, while for all $0 \neq i \neq j \neq 0$, we have:

$$\begin{aligned} \|\mathbf{p}_i - \mathbf{p}_j\|^2 &= \|\mathbf{p}_i - \mathbf{p}_0\|^2 + \|\mathbf{p}_j - \mathbf{p}_0\|^2 - 2[(\mathbf{p}_i - \mathbf{p}_0) \cdot (\mathbf{p}_j - \mathbf{p}_0)] \\ &= \|\mathbf{q}_i\|^2 + \|\mathbf{q}_j\|^2 - 2(\mathbf{q}_i \cdot \mathbf{q}_j) = \|\mathbf{q}_i - \mathbf{q}_j\|^2 \end{aligned} \quad (11)$$

Therefore, the new points are the same as the old up to translation and/or rotation, so that $\mathbf{q}_0, \dots, \mathbf{q}_N$ can be regarded as $\mathbf{p}_0, \dots, \mathbf{p}_N$ in a new coordinate system. Moreover, it follows from the orthogonality of the eigenvectors that these new coordinates are principal axes coordinates.

Although principal axes coordinates can be found more efficiently by diagonalizing the inertial tensor, the above method is applicable even if we do not have any coordinates for the points, but only the distances among them. The problem is that if the distances are inconsistent, the approximate Gram matrix $\tilde{\mathbf{G}}$ computed from the squared trial distances $\tilde{\mathbf{D}} = [\tilde{d}_{ij}^2]$ according to equation (8) will not be positive semidefinite of rank 3, and hence cannot be represented as a matrix of dot products among three-dimensional vectors. It can be shown, however, that if one sets all but the three largest eigenvalues to zero, then the matrix $\mathbf{G}$ obtained via equation (10) will be an optimum least-squares fit to $\tilde{\mathbf{G}}$ over all positive semidefinite rank 3 matrices.¹ It follows that the squared distances calculated from the coordinates

$$\|\mathbf{q}_i - \mathbf{q}_j\|^2 = g_{ii} + g_{jj} - 2g_{ij} \approx \tilde{g}_{ii} + \tilde{g}_{jj} - 2\tilde{g}_{ij} = \tilde{d}_{ij}^2 \quad (12)$$

will likewise be similar to the squared trial distances $\tilde{\mathbf{D}}$.

Note that the diagonal elements of the approximate Gram matrix $\tilde{g}_{ii} = \tilde{d}_{0i}^2$, which are just the squared trial distances involving the zeroth point, affect the fit to all the other

distances. This disproportionate influence can be eliminated by creating an additional point located at the centroid of the remaining N points, and treating it as the zeroth point. This is possible because the distances from the centroid to the remaining points can be calculated directly from the distances among them via the equation²⁹

$$\tilde{d}_{0i}^2 = \frac{1}{N} \sum_{j=1}^N \tilde{d}_{ij}^2 - \frac{1}{N^2} \sum_{j < k}^N \tilde{d}_{jk}^2 \quad (13)$$

Even so, the EMBED algorithm does not produce exactly a least-squares fit between the trial distances and those calculated from the coordinates. The coordinates obtained by embedding, however, can easily be improved by minimization of an appropriately weighted least-squares residual, using a method known as *majorization*.⁴

Because a variety of extremely efficient methods exist to locate the largest few eigenvalues and eigenvectors of a symmetric matrix without completely diagonalizing it, the EMBED algorithm is by far the fastest known way of finding reasonably good approximate coordinates to serve as starting points for further optimization.

3.4.3 Variations on Embedding

In the years since it was developed, the EMBED algorithm has been improved and extended in many ways, some of which have been touched on above. In this section several recent developments which promise to be useful in NMR structure determination are described.

The first of these methods is derived from early work by Crippen, who applied ideas from the EMBED algorithm to energy minimization.^{1,35} Since the EMBED algorithm can be viewed geometrically as projecting a higher dimensional structure onto a three-dimensional subspace, Crippen proposed minimizing the energy of the structures in spaces of successively lower dimension, eventually reaching a very low energy minimum constrained to three dimensions. He calls this approach *energy embedding*. Because even the simple conjugate gradients minimization of error functions converges quite reliably in four dimensions, it appears that only four dimensions are needed in applications of this approach to distance geometry. Unfortunately, it also turns out that the reduction of a four-dimensional structure to three dimensions is the most difficult step of the procedure, probably because it is in this step that the chirality and diastereomeric configuration of the molecule is determined.

Several investigators have found that by applying dynamical simulated annealing to four-dimensional error functions in which the sum of the squares of the fourth coordinates is added to the error as an additional restraint, the local minima encountered in reducing the structure to a three-dimensional one which satisfies the distance and chirality constraints can be overcome.^{4,14} At the same time, since atoms in the structure can pass through one another without the four-dimensional distance between them falling below the sum of their hard-sphere radii, the method appears to alleviate the local minimum problem encountered in three-dimensions significantly. Problems with local minima still occur, however, which can only be avoided by careful annealing.

Other, somewhat more analytic, approaches to reducing the dimension without violating the distance constraints are currently being explored. For example, in the *WARP procedure* recently developed by the author, this is done by using the elements of a 3×4 matrix $\mathbf{C}$ as the variables while holding the $4 \times N$ matrix of coordinates $\mathbf{P}$ fixed, thus seeking the minimum of the error function E over all projections and affine transformations:

$$\text{minimize } E(\mathbf{CP}) \quad \text{with respect to } \mathbf{C} \quad (14)$$

This minimization involves only 12 variables, and converges very rapidly. Although the error is only reduced by about a factor of 2 on average, the change in the coordinates can be very large. Thus, this method appears to provide an inexpensive means of improving the coordinates obtained by embedding.

Another extension of the ideas behind the EMBED algorithm is found in the work of Glunt, Hayden and co-workers. These investigators have developed a method, called *modified alternating projections (MAP)*, which reliably locates an $(N - 1)$ -dimensional structure that satisfies arbitrary self-consistent distance bounds.³⁶ This procedure involves repeated diagonalization of an $(N + 1) \times (N + 1)$ matrix, and hence is much more time consuming than EMBED. The MAP procedure, however, constitutes the most powerful general method yet developed for testing distance bounds for consistency, since if the bounds cannot be satisfied by an $(N - 1)$ -dimensional structure, they certainly cannot be satisfied by any three-dimensional structure. If it should prove possible to not only detect, but also isolate, inconsistencies by this method, it may be well worth the computer time required.

In addition, Glunt, Hayden and co-workers have developed an analogous procedure, called the *data box algorithm*, for refining three-dimensional structures versus both distance and chirality constraints.³⁷ This procedure may be summarized as follows:

1. Let $\tilde{\mathbf{D}}_0$ be a matrix of squared trial distances which satisfy the distance limits l_{ij} , u_{ij} (obtained from, for example, triangle bound smoothing), and use one iteration of MAP to find an $(N - 1)$ -dimensional structure $\mathbf{P}_0$ whose distances are a least-squares fit to $\tilde{\mathbf{D}}_0$.
2. Let $\mathbf{P}_1$ be a three-dimensional projection of $\mathbf{P}_0$, set $\tilde{\mathbf{D}}_1 = \tilde{\mathbf{D}}_0$ and $k = 1$.
3. Use a more efficient version of the majorization algorithm, called the *spectral gradient algorithm*, to obtain coordinates $\mathbf{P}_{k+1}$ whose distances $[d_{ij}] = [\|\mathbf{p}_i - \mathbf{p}_j\|]$ are a weighted least-squares fit to those in $\tilde{\mathbf{D}}_k$, and which minimize suitable chirality restraints.
4. Define $\tilde{\mathbf{D}}_{k+1} = [\tilde{d}_{ij}^2]$ according to

$$\tilde{d}_{ij} = \begin{cases} l_{ij} & \text{if } d_{ij} < l_{ij} \\ u_{ij} & \text{if } d_{ij} > u_{ij} \\ d_{ij} & \text{otherwise} \end{cases} \quad (15)$$

5. If the constraints are satisfied, stop; else set $k = k + 1$ and go to step (3).

With the most recent improvements in the spectral gradient algorithm, the efficiency and reliability of this procedure appears to be roughly comparable to the other methods discussed above.

4 THE CONTRIBUTIONS OF DISTANCE GEOMETRY TO NMR

Distance geometry has not only played an important role in NMR structure determinations, but has also been used to evaluate the efficacy of the geometric information available from NMR. This is done by simulating the constraints that could be obtained from NMR experiments of varying quality and completeness, computing a conformational ensemble for each such set of simulated constraints, and quantifying the precision of these ensembles by, for example, the RMSD (see Section 2.4). In this way, distance geometry has been able to assist NMR spectroscopists in deciding what kinds of experiment are most useful in determining structure, and thereby has played a role in the development of the experimental methodology. In this final section, we highlight some of the contributions of this approach to present-day methods for determining protein structure from NMR.

The original motivation for distance geometry was to develop a formalism for representing the structural information available from a wide variety of experimental and theoretical methods, together with computational methods for determining biomolecular conformation from this information.³⁰ As part of this larger effort, the simulation method described above was used to evaluate the distance constraints available from a number of possible experiments on protein structure, using a simple 'one point per residue' model (which was about all the computers available at that time could handle).³⁸ The most interesting result of this study was that it is better to know many distances imprecisely than it is to know a few distances precisely. In particular, a complete list of all contacts (<1 nm) and noncontacts (>1 nm) present in a globular α -carbon chain was found to be sufficient to determine all its distances to within only 0.1 nm on average. An important implication of these results, which had a substantial influence on subsequent events, is that the information available from the NOESY experiment should be a powerful constraint on the tertiary structure of proteins.

Because the density of constraints available from NOESY at that time was significantly lower than that used in these simulations, and because it was not immediately certain how well the results would extend to more detailed atomic models of proteins, a similar study was later performed using both a more detailed atomic model as well as constraint sets which mimicked those available from a wide variety of solution NMR experiments.³⁹ The conclusions of this latter study not only supported the earlier results, but were actually a good deal better than expected. The reason for this, as is now known, is that a more detailed atomic model enables one to represent the intrinsic rigidity of the polypeptide chain and the steric restrictions on how the interior side chains can be packed together much more accurately than a one-point-per-residue model. The results of this study also enabled us to formulate some general guidelines concerning the optimum strategy for determining a protein structure from NMR data, which may be summarized as follows:

1. In determining the large-scale tertiary structure of a protein's polypeptide backbone, it is much more important to maximize the quantity of interresidue distance constraints than it is to maximize the quality (i.e. precision) of those constraints; sequential, intraresidue and torsion angle constraints play only a secondary role in this regard.

2. In order to determine the 'local' conformation of short segments of the polypeptide chain and their side chains with adequate precision, relatively precise sequential and intraresidue distance constraints are needed; torsion angle constraints derived from coupling constants are also, of course, very useful.

Since stereospecific assignments were not usually available at the time these studies were performed, their effect was not evaluated at that time. Once they became widely available, however, further studies were performed which showed they made a surprisingly strong contribution to the precision, particularly of the local conformation.^{4,8} In part this is due to the elimination of 'pseudoatoms' and the consequent corrections to the distance constraints, but a more significant contribution seems to be due to the directionality information that these assignments provide.

Even though sophisticated refinement methods involving 'back-calculation' of the NOESY cross-peak intensities are coming into use which promise further to enhance the precision of NMR structure determinations,⁴⁰ distance geometry may be expected to continue to play an important role in the overall structure determination process. In the first place, it is a suitable formalism in which to eliminate errors from the data, determine its intrinsic structural implications, and to establish the basic features of the conformation. In the second, since these more complex refinements are ill-conditioned and extremely prone to becoming trapped by local minima, the excellent starting conformations that distance geometry yields are essential if they are to succeed. Finally, whereas these refinements all assume that the solution 'structure' can be adequately summarized by a single conformation, in reality the solution structure is an ensemble of rapidly exchanging conformations. The conformational ensembles that distance geometry yields are therefore a potentially more accurate representation of the solution structure, and in time methods may be developed which enable us to generate or refine these ensembles so as to make them representative of the actual solution ensemble.⁴¹

Several more detailed reviews covering the applications of distance geometry to structure determination by NMR are available.⁴²⁻⁴⁶

1 INTRODUCTION

Enzyme-catalyzed reactions of adenosine triphosphate (ATP) (Figure 1) are ubiquitous in biochemistry, occurring in almost all metabolic pathways. Chemically, such reactions are nucleophilic substitutions at either the α , β , or γ phosphorus atoms of ATP by an oxygen or, rarely, by an amine nitrogen.¹ Substitution at the P- α , which results in the departure of pyrophosphate as the leaving group, is common in biochemistry occurring on hundreds of enzymes including polymerases, cyclases, and synthetases. Substitution at P- β , which results in the leaving of AMP, is very rare with only seven known examples.² The rarity of these reactions may well result from the greater electron density at P- β as detected by its 13 ppm low-frequency (upfield) shift from P- α by ^{31}P NMR.³ Substitution at P- γ which results in the leaving of ADP is very common, occurring on hundreds of enzymes including kinases, ATP hydrolases, and synthetases (Figure 1). All enzyme-catalyzed reactions of ATP require at least one divalent cation for activity and ATP is present in cells predominantly ($\sim 80\%$) as its Mg^{2+} complex.⁴ Hence structural studies of ATP and its metal complexes were among the earliest biochemical applications of NMR.^{3,5} Major questions addressed by NMR are whether the mechanism of substitution is dissociative [equation (1)] or associative [equation (2)] and the precise role of the divalent cation activator.

Figure 1 Sites of enzyme-catalyzed bond cleavage of ATP (modified from reference 1)

NMR methods have long been used to determine the conformations and arrangements of enzyme-bound substrates,⁶ intersubstrate distances,⁷ motion at enzyme active sites,⁸ rates of exchange of bound with free substrate⁹ and, more recently, the solution structures of ATP-utilizing enzymes¹⁰⁻¹² and of functional fragments of such enzymes which retain the ability to bind substrates.¹³⁻¹⁶ The NMR docking procedure has been developed to locate the substrate binding site in the X-ray structure of several enzymes, including the ATP-utilizing enzymes adenylate kinase and DNA polymerase.^{14,17-19}

2 NMR PARAMETERS USEFUL IN THE STUDY OF ATP-UTILIZING ENZYMES

In addition to the fundamental parameters of the NMR spectrum (chemical shifts, coupling constants, and intensities of resonances) that form the basis of resonance assignments, three relaxation rates are found to be especially valuable in the study of enzyme mechanisms. These are the longitudinal relaxation rate ($1/T_1$), which is used to measure metal-nucleus distances, the nuclear Overhauser effect (NOE), which is used to measure interproton distances, and the transverse relaxation rate ($1/T_2$), which is used to measure dissociation rates of enzyme-substrate and enzyme-product complexes.

Paramagnetic effects of transition metals on $1/T_1$ of protons, ^{31}P , ^{13}C , and ^{19}F have long been used to measure distances from the metals to these nuclei on enzymes, and enzyme-bound substrates, in the so-called paramagnetic probe- T_1 method.^{9,20,21} The longitudinal relaxation rate ($1/T_1$), defined as the first order rate constant for orientation of a set of nuclear magnetic vectors along the direction of the magnetic field, is increased by the unpaired electrons of nearby transition metals or free radicals, by an amount inversely related to the sixth power of the distance (r) between the unpaired electrons and the nucleus. The relevant equation is

$$r = C \left[\left(\frac{qfT_{1P}T_{o.s.}}{T_{o.s.} - T_{1P}} - \tau_M \right) \left(\frac{3\tau_c}{1 + \omega_I^2\tau_c^2} + \frac{7\tau_c}{1 + \omega_S^2\tau_c^2} \right) \right]^{\frac{1}{6}} \quad (3)$$

where C is a product of known physical quantities, q is the relative stoichiometry of bound paramagnet and bound substrate, f is the concentration ratio of bound paramagnet to total substrate, T_{1P} is the paramagnetic contribution to

T_1 , $T_{o.s.}$ is the outer-sphere relaxation time, τ_M is the lifetime of the complex, τ_c is the correlation time for dipolar interaction, ω_I is the nuclear precession frequency and ω_S is the electron precession frequency. As discussed in detail elsewhere,^{20,21} the measurement of distances by this method requires the experimental determination of four other parameters in the relaxation equation, namely q , $T_{o.s.}$, τ_M , and τ_c , which can usually be done in the same or in a closely related experiment. Introduced into biochemistry in a study of MnATP interactions,⁵ the paramagnetic probe- T_1 method was first tested and shown to give the correct distance in the simpler binary $Mn^{2+}-F^-$ complex,⁹ and was also extended to enzyme-metal-substrate complexes.⁹ Since then, numerous comparisons of distances determined by this method with those determined by X-ray have shown its validity, when properly applied, in measuring distances as great as 2.4 nm.

The NOE can be used to measure the distance between pairs of magnetic nuclei. The NOE is defined as a change in the intensity of an NMR resonance observed after pre-irradiating another resonance. The magnitude of this change in resonance intensity, multiplied by the longitudinal relaxation rate of the resonance undergoing the change (the cross-relaxation rate) is, under certain circumstances, inversely proportional to the sixth power of the distance between the nuclei.²²⁻²⁵ The relevant equation for a two spin system assuming instantaneous saturation of resonance B is

$$f_A(B)_t = \frac{\sigma_{AB}}{\rho_A} (1 - e^{-\rho_A t}) \quad (4)$$

where $f_A(B)_t$ is the fractional change in intensity of A after pre-irradiating B for time t , σ_{AB} is the cross-relaxation rate and ρ_A is the longitudinal relaxation rate ($1/T_{1A}$) of A. The experimentally measured values of $f_A(B)_t$ and ρ_A are fitted to equation (4) to evaluate σ_{AB} which is related to the internuclear distance between A and B (r_{AB}) by equation (5)

$$r_{AB} = \frac{\gamma^4 \hbar^2}{10r_{AB}^6} \left(\frac{6\tau_r}{1 + 4\omega_I^2 \tau_r^2} - \tau_r \right) \quad (5)$$

where γ is the gyromagnetic ratio, $\hbar$ is Planck's constant divided by 2π , τ_r is the time constant for reorientation of the internuclear vector r_{AB} and ω_I is the nuclear precession frequency. On taking a time derivative of equation (4) and setting $t = 0$ it is seen that the initial slope of $f_A(B)$ as a function of time directly gives σ_{AB} . Hence it is not always necessary to measure ρ_A if early time points are measured. Early time points are desirable for measuring interproton distances to avoid the effects of spin diffusion, since primary NOEs develop more rapidly than higher order effects.²⁵⁻²⁷ The NOE method has been used qualitatively to detect proximities between pairs of protons,²³ and quantitatively to measure relative^{26,27} and absolute interproton distances¹⁷ ranging from 0.2 to 0.5 nm. The measurement of absolute interproton distances, which requires the determination of NOEs at two magnetic fields, has established the validity of this method since it yielded the correct interproton distance from H-1' to H-2' of MgATP.^{17,26} A more comprehensive treatment of the data may be carried out, taking into account, where possible, all relaxation pathways²⁸ often with comparable results, within experimental error.

The transverse relaxation rate ($1/T_2$) is the rate constant for dephasing of nuclear magnetic vectors in a direction

perpendicular to the applied magnetic field. Paramagnetic effects of enzyme-bound metals on $1/T_2$ of substrates have long been used to measure the exchange rates of ($1/\tau_M$) of enzyme-bound substrates with free substrates,²⁰ based on a relationship derived by Swift and Connick²⁹ which simplifies to

$$\frac{1}{fT_{2P}} = \frac{q}{T_{2M} + \tau_M} + \frac{1}{T_{o.s.}} \quad (6)$$

when the paramagnetic shift is small. In equation (6) T_{2M} is the transverse relaxation time in the paramagnetic complex. Analysis of the temperature dependence of $1/fT_{2P}$ is used to obtain the exchange rate or a lower limit to it.^{20,21} These exchange rates are usually dominated by the rate of dissociation of the enzyme-substrate complex. Comparisons of the exchange rates of enzyme-substrate and enzyme-product complexes measured by $1/T_2$ with those determined by transient state and steady state kinetics provide a critical test of whether the complex, studied by NMR, dissociates rapidly enough to participate in catalysis.

The combined use of both the paramagnetic probe- T_1 method to measure metal-nucleus distances, and the NOE method to measure interproton distances, on an enzyme-bound flexible substrate, such as ATP, provides a rigorous way of defining both the conformation²⁶ of the bound substrate and the uniqueness of the conformation. Measurement of the dissociation rate of the enzyme-substrate complex by $1/T_2$ provides a test of its kinetic competence to participate in catalysis.^{9,20,21}

The NMR docking procedure which is used to position the substrate such as ATP into the X-ray or NMR determined structure of an enzyme, consists of four steps:^{17-19,30}

1. Determine the conformation of the enzyme-bound substrate by NMR measurements of metal-nucleus distances and interproton distances.
2. Measure distances from a paramagnetic reference point on the enzyme (or substrate) to assigned proton resonances of the substrate (or enzyme).
3. Identify amino acid residues of the enzyme within 0.5 nm of the bound substrate by intermolecular NOEs from assigned proton resonances of the enzyme to those of the substrate.
4. Use the distances from (2) and (3) to position the proper conformation of the substrate into the X-ray or NMR structure of the enzyme, removing steric overlaps by energy minimization of the complex.

An additional step, to confirm the location of the active site, is to design and synthesize a peptide, approximately 50 residues in length, based on the presumed location of the bound substrate, and to determine whether this peptide binds substrate with an affinity comparable to that of the enzyme. This step has been carried out with adenylate kinase¹⁷, DNA polymerase,¹⁴ and F1 ATPase.^{15,16,31}

3 STRUCTURE OF METAL-ATP COMPLEXES

Because of the high concentrations of Mg^{2+} in cells, ranging from 3.5 to 8.5 mM, the cellular form of ATP is predominantly ($\geq 80\%$) MgATP, as determined by the ^{31}P chemical shifts of ATP in various cell types.⁴ Hence for most ATP reactions, Mg^{2+} is the physiological activator although, in vitro, other

cations can substitute for Mg^{2+} . In free MgATP , as determined by ^{31}P chemical shifts^{32,33} $^2J_{\text{PP}}$ coupling constants³³ and by T_1 values of ^{17}O bonded to phosphorus,³⁴ Mg^{2+} is simultaneously coordinated to all three phosphates, although somewhat more weakly to the α -phosphate. MnATP has a very similar structure as found by paramagnetic effects on T_1 of the phosphorus atoms.^{5,35,36} The metal ions do not interact with the adenine ribose portion of ATP. Because of the flexibility of ATP, the structure of free metal-ATP in solution is a mixture of at least three conformations of the adenine ribose portion (Figure 2),²⁶ and four stereoisomers of the metal triphosphate portion, two at each of the chiral α - and β -phosphorus atoms.^{37,38}

4 STRUCTURE OF ENZYME-BOUND METAL-ATP COMPLEXES

With enzyme-bound metal-ATP, the structure becomes much simpler, since the protein lattice constrains the conformations and stereoisomers of this flexible substrate usually to a single species.^{26,35,36,39} Figure 2 summarizes the structures of metal-ATP found on several enzymes based on NMR as well as kinetic studies with substitution inert complexes of ATP with the trivalent metal ions Co(III) and Cr(III) ,³⁷ and with α - and β -thio-ATP complexes of hard and soft divalent cations.³⁸ As also indicated in Figure 2, those enzymes which significantly alter the glycosidic torsional angle of ATP from those found in the free nucleotide show high selectivity for a specific nucleotide base.

On enzyme-bound metal-ATP, the metal is always found to be coordinated to the γ -phosphate, almost always to the β -phosphate and sometimes to the α -phosphate as well. These locations of the metal ions on ATP have been found on all enzymes investigated, regardless of which phosphorus atom of ATP undergoes nucleophilic displacement and which bond undergoes cleavage in the catalyzed reaction. Hence the position of the metal does not determine the site of bond cleavage in ATP.³⁹⁻⁴¹

The remainder of this article will consider individual examples of ATP enzymes which catalyze nucleophilic substitution at either the α , β , or γ phosphorus atoms.

5 α -SUBSTITUTION: DNA POLYMERASE I

The DNA polymerase reaction involves substitution at the α -P of deoxynucleoside triphosphate (dNTP) substrates by the 3'-OH group of the growing DNA strand or primer, with displacement of pyrophosphate. It utilizes four nucleotide substrates for elongation of the primer in a manner consistent with Watson-Crick base pairing between the incoming substrate and template. DNA polymerase I (pol I), the first enzyme found to catalyze such a reaction⁴² is a single polypeptide of 928 amino acids consisting of three catalytic domains (Figure 3). The amino-terminal domain (residues 1 to 325) catalyzes a 5',3'-exonuclease reaction, the middle domain (residues 326 to 524) catalyzes a proofreading 3',5'-exonuclease which contributes to the fidelity of template copying, and the carboxy-terminal domain (residues 543 to 928) catalyzes the polymerase reaction. The middle- and

carboxy-terminal domains (residues 326 to 928) together constitute the Klenow or large fragment of pol I for which an X-ray structure has been determined.^{43,44} NMR studies of pol I and its large fragment have concentrated on the polymerase active site. An early measurement of distances from Mn^{2+} bound at the polymerase site to the substrates dTTP and dATP in abortive enzyme- Mn^{2+} -substrate complexes by ^{31}P and ^1H relaxation revealed metal coordination to the γ -phosphate and nucleotide conformations suggestive of B-form DNA.³⁵ B-like conformations of bound dTTP and dATP were confirmed in ternary Mg^{2+} complexes by NOE measurements of interproton distances which yielded high *anti* O-1'-*endo* substrate conformations.⁴⁵⁻⁴⁷ The presence of templates (RNA rather than DNA templates were used to avoid their hydrolysis by the 3',5'-exonuclease) had little effect on the conformations of bound dTTP or dATP. NOE studies also indicated the bound RNA templates (rU)₅₄, (rA)₅₀, and (rC)₃₇ to have B-like conformations on pol I. Because of their greater tendencies to form *syn* conformations, the substrates dGTP and ddGTP showed a mixture of *syn* (40%) and *anti* (60%) conformations on DNA polymerase. The binding of templates simplified these conformations to a single B-like, high *anti*-O-1'-*endo* species, suggesting base pairing between the template and the bound substrate.

Such conformational adjustments of the bound substrate and template into a B-like conformation could contribute to the low error rate in template replication achieved by this enzyme of approximately 10^{-6} fold, i.e. one error per 10^6 correct nucleotides incorporated. It has been estimated that Watson-Crick base pairing contributes a factor of $\sim 10^{-2}$ to the error rate, the proofreading 3',5'-exonuclease contributes $\sim 10^{-1}$, and an error prevention step preceding incorporation contributes 10^{-3} . The nature of this error prevention step is under active investigation. Templates do not alter the relative affinities of pol I for complementary and noncomplementary substrates as found by competitive titrations monitored by NMR line broadening.^{46,47} Hence the error prevention step increases the relative velocity of incorporation of the correct substrate over the incorrect substrate. The abortive enzyme-Mn-dTTP complex showed only γ -phosphate coordination³⁵ while the active complex shows β -coordination as well.⁴⁸ Hence a selective structural change occurring only with the correct substrate may involve β -coordination by the enzyme-bound divalent cation, closing the chelate ring to the leaving pyrophosphate group.^{41,46} Model building of the B-like conformation of the Mg dNTP substrate determined by NMR into B-DNA showed the α -P of the substrate to approach the 3'-OH of the primer terminus at a distance appropriate for an associative displacement (< 0.49 nm), with inversion at phosphorus.^{41,47} Such inversion, first predicted by NMR,³⁵ was subsequently established by stereochemical analysis of the polymerase reaction.⁴⁸

Another question addressed by NMR was the amino acid environment of the active site for polymerization. Intermolecular NOEs from the enzyme to protons of the substrate dATP carried out by one-dimensional (1D) NMR studies at 250 MHz and recently confirmed by NOESY spectra at 600 MHz revealed the proximity of bound dATP to hydrophobic and aromatic residues, most likely Leu, Ile, and Tyr.⁴⁵⁻⁴⁷ These results were consistent with photoaffinity labeling studies with 8-azido dATP⁴⁹ which modified Tyr-766 located in the sequence L-I-Y-G which is conserved among

Enzyme		Base specificity
None		—
Pyruvate kinase		Low
Protein kinase		High
DNA polymerase I		High (template directed)
RNA polymerase		High (template directed)
PP-RIB-P Synth		High
Adenylate kinase		High

Figure 2 Conformations, expressed as glycosidic torsional angles, and location of metals on free and enzyme-bound ATP, and correlation of conformation with nucleotide base specificity as determined by kinetic studies (modified from reference 39)

Figure 3 Position of the metal-nucleotide substrate in the X-ray structure of DNA polymerase I^{43,44} based on transferred NOEs,^{45–47} photoaffinity labeling,⁴⁹ and substrate binding properties of an active site peptide.⁵¹ Also shown are the locations of tight (T) and weak (W) binding sites for divalent cations.⁵⁰ The broken circle depicts the 5',3'-exonuclease domain

DNA polymerases. These and other chemical modification studies permitted docking of the substrate into the X-ray structure of the enzyme with the adenine ring along the O-helix where these residues are located (Figure 3).^{47,50} NOEs from the enzyme to bound RNA templates were consistent with nearby Arg and/or Lys residues.

As an independent test of the substrate location, two peptides were synthesized and investigated for substrate binding.⁵¹ Peptide I, based on residues 728 to 777 of the pol I sequence encompassed both the N and O helices (Figure 3). Peptide II, based on residues 840 to 888 contained the conserved sequence V-H-D-E, including His-881 which was photoaffinity labeled by TTP. It consisted of the Q helix and β strands 12 and 13 of the X-ray structure. While both peptides retained significant secondary structure as found by circular dichroism (CD), only peptide I was able to bind substrates and substrate analogs with affinities approaching those of the complete enzyme. Like the complete enzyme, peptide I also bound duplex DNA tightly, forming a ternary peptide-DNA-dNTP complex, providing strong evidence for the location of the polymerase active site (Figure 3).⁵¹

The solution structure of peptide I was determined by two-dimensional (2D) ¹H NMR¹⁴ and, like other peptides, was found to consist of both extended and partially folded structures which equilibrated rapidly on the NMR timescale. The N-helix of the enzyme was replaced by four β -turns which may be intermediates in helix formation. The O-helix of the enzyme was replaced by a loop in the peptide. A residue-by-residue comparison of individual amino acid conformations revealed that only 36% of the enzyme conformation is retained by the peptide, a typical result for peptides. The homologous L-I-Y-G sequence, which was found by NOEs to water protons to be exposed to the solvent, contributes to the substrate binding

site. An exposed cluster of cationic residues, three Arg and one Lys, probably represents the DNA binding site of the peptide.⁵¹

The conformations and arrangement of substrates at the active site of RNA polymerase have also been investigated by NMR and these studies have been reviewed.⁵²

6 β -SUBSTITUTION: THE Mut T ENZYME

Of the seven known enzymes which catalyze nucleophilic substitution at the electron rich P- β of ATP,² most and possibly all require two divalent cations for catalytic activity, one directly coordinated by ATP, and the other by the enzyme.⁵³ The enzyme-bound metal also interacts with the metal-ATP complex, presumably to further activate the P- β for nucleophilic attack. The Mut T enzyme, the simplest of these enzymes, catalyzes the hydrolytic cleavage of nucleoside triphosphates to yield the nucleotide and pyrophosphate. While active with all NTPs, its biological role in *E. coli* and man is to cleave mutagenic dNTPs such as 8-oxo-dGTP which has a 10^3 -fold lower K_M value than do other nucleotides.^{54,55} When Mut T is inactivated by mutation, *E. coli* accumulates a large number of A $\cdot$ T $\rightarrow$ C $\cdot$ G transversions during DNA replication.^{56,57}

When the Mut T-catalyzed hydrolysis of dGTP was carried out in H₂ ¹⁸O, and monitored by ³¹P NMR at 243 MHz, the label appeared in pyrophosphate as indicated by an 0.01 ppm low-frequency shift of the ³¹P resonance of pyrophosphate, but not of dGMP, thus establishing nucleophilic substitution by H₂O at P- β .² Kinetic analyses of the Mn²⁺ and Mg²⁺ activated enzyme indicated a dual divalent cation requirement.⁵³ Binding studies with Mn²⁺ and with the non-hydrolyzable substrate analog, α,β -methylene adenosine triphosphate (AMPCPP),

monitored by $1/T_1$ of water protons, confirmed two Mn^{2+} binding sites, one on the enzyme and the other on the AMPCPP. Mutual tightening of binding of Mn^{2+} and MnAMPCPP to the enzyme, and the decrease in the enhanced longitudinal relaxation rate of water protons due to $\text{E} \cdot \text{Mn}^{2+}$, upon binding of MnAMPCPP , suggested a metal bridged $\text{E}-\text{Mn}^{2+}-\text{AMPCPP}-\text{Mn}^{2+}$ complex.⁵³

The small size (129 residues) and stability of this enzyme permitted the study of its solution structure by heteronuclear multidimensional NMR.^{11,12} ^{15}N labeling of the enzyme permitted $^1\text{H}[^{15}\text{N}]$ heteronuclear single quantum coherence (HSQC), $^1\text{H}[^{15}\text{N}]\text{TOCSY-HMQC}$, and $^1\text{H}[^{15}\text{N}]\text{NOESY-HMQC}$ experiments, and ^{15}N and ^{13}C labeling permitted HNCA, HN(CO)CA, HNCO, constant time $^1\text{H}[^{13}\text{C}]\text{HSQC}$, HCACO, and HCA(CO)N experiments. These and other experiments led to the complete sequence-specific assignment of the backbone HN, N, C- α , H- α and CO resonances of the free enzyme,¹¹ and elucidated the secondary structure which consists of two α -helices, a five stranded, mixed β -sheet containing two β -turns, and four loops (Figure 4).¹² Mixed β -sheets are found in other highly stable proteins such as ubiquitin.⁵⁸

The active site, as studied by changes in chemical shifts in the $^1\text{H}[^{15}\text{N}]\text{HSQC}$ spectrum in response to the addition of Mg^{2+} , subtends loops I and III, the end of helix I and β -strands A and B. Subsequent titration with MgAMPCPP showed chemical shift changes in the same regions, but most notably in residues A27, M29, A30, N31, K39, and I40 of loop I. Titration with $\text{Mn}^{2+}\text{AMPCPP}$, a distance-dependent probe, resulted in the paramagnetic broadening of HN and ^{15}N cross peaks of residues G37, G38, and K39 of Loop I and G59 at the end of helix I.¹² In accord with these findings, residues in loop I and in the C-terminus of helix I show homologies with other anti-mutator enzymes, and mutations in loop I such as E34K and E38D markedly decrease enzymatic activity.⁵⁷

NMR studies have also been made on the conformation and arrangement of substrates at the active site of phosphoribosyl

pyrophosphate synthetase, another β -enzyme, and have been reviewed.³⁹

7 γ -SUBSTITUTION: cAMP-DEPENDENT PROTEIN KINASE

One of the most important members of this vast group of enzymes which catalyze substitution at P- γ of ATP is cAMP-dependent protein kinase, an enzyme which controls the rates of many other enzymes and of entire metabolic pathways.^{59,60} The resting holoenzyme exists as an inhibited complex (R_2C_2) of the regulatory dimer (R_2) and two catalytic subunits (C). The binding of cAMP to four sites on the regulatory dimer increases the dissociation constant of R_2C_2 by $\sim 10^4$ fold resulting in the release of two molecules of the catalytic subunit which is the active enzyme.^{60,61} This enzyme catalyzes the phosphorylation, by MgATP , of Ser and Thr residues on proteins and peptides with the preferred sequence -Arg-Arg-X-Ser-Y- in which X is almost any residue and Y is hydrophobic. Magnetic resonance studies of this enzyme have examined the role of the divalent cation,⁶² the conformations and arrangement of enzyme-bound substrates,^{26,63} the mechanism of phosphoryl transfer by the catalytic subunit,⁶⁴ the bound phosphorus of the regulatory subunit,²⁵ and the mechanism of inhibition of the catalytic subunit by the regulatory subunit.⁶¹ The coordination scheme of the active ternary complex of the enzyme, metal, and ATP is a nucleotide bridge complex $\text{E}-\text{ATP}-\text{M}^{2+}$ as shown by kinetics and by Mn^{2+} and ATP binding studies monitored by $1/T_1$ of water protons.⁶² The binding of Mn^{2+}ATP to the enzyme induced the formation of a second and weaker Mn^{2+} binding site which partially inhibited the enzyme. Mn^{2+} at this inhibitory site bridged the enzyme to the three phosphates of the metal-nucleotide substrate in a complex of the form

These two divalent cation binding sites were used separately as reference points from which distances were determined to both ATP and peptide substrates by the paramagnetic probe- T_1 method.^{63,65} These distances, together with interproton distances measured by the NOE method²⁶ yielded a single, high *anti*-O-1'-*endo* conformation for bound $\text{Co}^{3+}(\text{NH}_3)_4$ ATP. Intersubstrate distances from two paramagnetic reference points, Mn^{2+} at the inhibitory site and Cr^{3+} at the activating site, were used to determine the conformation of the optimal heptapeptide substrate LRRASLG and its Tyr-4 and Ala-5 analogs. A total of 31 measured metal-proton distances were used in model building to explore the allowed conformations of the enzyme-bound heptapeptide substrate. The distances were incompatible with a helix, β -strand, β -bulge, or all possible β -turns within the bound heptapeptide. They were consistent only with two extended coil structures,⁶³ one of which could be ruled out by kinetic and model building studies of *N*-methylated peptides.⁶⁶ The *anti* conformation for bound ATP and the extended coil conformation for the bound substrate (Figure 5) were confirmed by X-ray diffraction.^{67,68} Extended coil conformations of bound peptide and protein

Figure 4 Diagram of the secondary structure of Mut T based on heteronuclear multidimensional NMR studies^{11,12}

Figure 5 Coil conformation of the enzyme-bound heptapeptide substrate LRRASLG at the active site of cAMP-dependent protein kinase, based on NMR-determined distances from Cr^{3+} -ATP and Mn^{2+} .^{63,66} (modified from reference 63)

substrates have been found at the active sites of many other enzymes including glyoxalase I, glutathione reductase, and each of the four classes of proteases. Such extended substrate conformations would permit greater interaction with the enzyme thereby contributing to enzyme specificity.⁶³

^{31}P NMR studies of the regulatory dimer (R_2) revealed broad resonances assigned to tightly bound, highly immobilized cAMP and narrow resonances assigned to covalent, mobile phosphoserine signals. One of these phosphoserine signals was removed by the catalytic subunit and an ADP regenerating system, confirming that R_2 is a substrate of the catalytic subunit.²⁵ Accordingly, in R_2C_2 the access of peptide substrates to the active site was blocked while metal-ATP was freely accessible. On adding cAMP, which dissociated R_2C_2 , peptide binding at the active site was detected by paramagnetic effects of Mn^{2+} on the relaxation rates of the peptide protons.⁶¹ Thus the regulatory dimer is a tightly bound substrate which inhibits the catalytic subunit by occluding the peptide or protein-binding site but not the ATP-binding site.

8 γ -SUBSTITUTION: ADENYLATE KINASE

This small and ubiquitous enzyme which catalyzes the reaction

has been studied by X-ray^{69,70} and NMR.^{10,13,17,71,72} An early NMR study of the ATP complex of adenylate kinase detected a NOE from the C-2 proton of His-36 to the adenine H-2 resonance of MgATP,⁷¹ placing the binding site of ATP near two regions of amino acid sequence which were homologous with those found on numerous ATP-binding enzymes.⁷³ This proximity was confirmed by a distance of $12.9 \pm 1.0 \text{ \AA}$ from Cr^{3+} of Cr^{3+} -ATP to this histidine proton

of the enzyme.¹⁷ A synthetic peptide based on residues 1–45 of adenylate kinase which contained the first of these homologies GX_4GKGT was found to bind MgATP with an affinity and in a conformation very similar to those found on the complete enzyme.¹⁷ The solution structure of this peptide, determined by 2D proton NMR methods,¹³ revealed two transient helical regions and three stretches of β -strand. A residue-by-residue comparison with the corresponding region in the X-ray structure of the enzyme showed the retention of 42% of the secondary structure in the peptide. The binding of MgATP resulted in conformational changes in the peptide backbone with an overall decrease in its structural content, suggestive of the effects on the enzyme of binding MnATP .⁶⁹ The conformation of enzyme-bound AMP was found to be high-*anti*-3'-*endo*-2'-*exo* both by intramolecular NOEs and by intersubstrate distances from enzyme-bound Cr^{3+} -AMPPCP. This high energy conformation was consistent with the high specificity of adenylate kinase for AMP.⁷² The intersubstrate distances on the enzyme also yielded a reaction coordinate distance of $\geq 3 \text{ \AA}$ from the γ -phosphorus of Cr^{3+} -AMPPCP to the entering phosphate oxygen of AMP, consistent with an associative mechanism of phosphoryl transfer.⁷² The orientation of MgATP on the peptide¹⁷ differs from that found on the complete enzyme.^{10,70} This is not surprising since other portions of the binding site are not present in the peptide. The backbone NMR assignments of adenylate kinase, the solution secondary structure, and the binding site for the bisubstrate analog $\text{AP}_5\text{-A}$ have been reported¹⁰ and they generally agree with the crystal structure.⁷⁰

9 γ -SUBSTITUTION: F1 ATPASE, ACTIVE SITE PEPTIDE

The synthesis of ATP from ADP and inorganic phosphate (Pi) in oxidative phosphorylation utilizes the enzyme F1 ATPase, which is driven in reverse by a proton electrochemical gradient generated by respiratory electron transport. The enzyme is huge (RMM 371 000) with an $\alpha_3\beta_3\gamma\delta\epsilon$ composition of subunits which are symmetrically arranged, as found by X-ray diffraction at 0.36 nm resolution.⁷⁴ As found by chemical modification and mutagenesis, the active sites for ATP hydrolysis and formation reside on each of the three β -subunits.⁷⁵ F1 ATPase shows two regions of sequence homology with other ATP or GTP binding enzymes adenylate kinase, *ras*, *recA*, and myosin.⁷³ This homology and the location of the ATP-binding site on adenylate kinase by the NMR study of an appropriate peptide¹⁷ led to the proposal that the active site of F1 ATPase corresponded to that of adenylate kinase.⁷⁶ Accordingly, a 50-residue peptide, PP-50, based on residues 141–190 of the β -subunit of F1 ATPase which contained the homologous sequence GX_4GKT was synthesized and was found to bind ATP tightly.³¹ The solution structure of PP-50 was determined by 2D NMR at pH 4.0 which improved the solubility and retained the tight binding of ATP.¹⁵ The structure was found to be labile, containing two transient β -turns and some transient tertiary structure detected by remote NOEs. The peptide-ATP complex was not soluble enough for study by NMR, but CD studies showed that ATP binding increased the structure of the peptide.¹⁵ Titration of PP-50 with trifluoroethanol (TFE) increased the helix content

Figure 6 Diagram of the secondary structure and ATP-binding site of PP-50, a peptide based on residues 141–190 of F1 ATPase. Broken lines indicate proximities based on intermolecular ROEs and on paramagnetic effects of Cr^{3+} ATP on TOCSY spectra.¹⁶ Shaded area shows GX₄GKT homology sequence

to 29% with an end point at 23.5% TFE, as detected by CD spectroscopy. TFE also increased the affinity of PP-50 for ATP to a value ($K_D = 7.3 \mu\text{M}$) approaching that of the intact enzyme ($K_D = 1.2 \mu\text{M}$) and increased the solubility of the PP-50–ATP complex, permitting the determination of its solution structure by 2D ^1H NMR.¹⁶ The structure of PP-50 in 25% TFE consists of a coil (residues 1–8), an extended strand (residues 9–12), a loop (residues 13–22) containing the GX₄GKT homologous sequence (residues 16–23), a long α -helix (residues 23–36), a β -turn (residues 38–41) and a coil (residues 42–50) (Figure 6). No change in the structure of PP-50 occurred on the binding of ATP or MgATP, as detected by NOESY and CD spectra. NOEs and rotating frame Overhauser effects (ROEs) indicated an *anti* conformation for bound ATP. Intermolecular ROEs showed the adenine ribose portion to bind near the hydrophobic residues L3, P5, Y6, G9, V33, F43, G45, and V46. Paramagnetic effects of β,γ -bidentate Cr^{3+} ATP on TOCSY spectra of PP-50 showed the metal–triphosphate moiety to bind near K22 of the GX₄GKT loop, as found on adenylate kinase^{17,70} and on an active site peptide based on adenylate kinase.^{13,17} A hydrophobic environment for bound MgATP on F1, as found on PP-50,¹⁶ would thermodynamically favor its formation from MgADP and P_i . The subsequent release of ATP from F1 could be driven conformationally by the discharge of the proton electrochemical gradient.^{16,76} These structural findings are consistent with kinetic studies of site-directed mutants of F1 ATPase.⁷⁷

1 INTRODUCTION

Peroxidases form a class of enzymes, an extensive subgroup of which consists of heme proteins. Out of the entire peroxidase superfamily, it is the heme peroxidases which have been most thoroughly studied by NMR, and they will be the focus of this article (Figure 1). Increasing attention has been devoted to NMR studies of heme peroxidases over the past decade, and no attempt will be made here to present a comprehensive review. Rather, selected examples, illustrative of specific problems that have been amenable to NMR study, will be presented. The majority of these examples will focus on proton NMR studies of horseradish peroxidase (HRP) and yeast cytochrome-*c* peroxidase (CcP), because these two proteins have been studied in the greatest detail to date. For NMR spectroscopists to appreciate both the problems and achievements facing those who work with peroxidases, a brief introduction to peroxidases, their chemistry, their structure and the effects of paramagnetism (characteristic of heme peroxidases) upon NMR spectra will be presented with appropriate references for those interested in details.

Peroxidases are widespread in nature,^{1–5} catalyzing the hydrogen peroxide oxidation of such varied substrates as simple organic and inorganic compounds, lignin, coordination compounds, amino acids, halide ions, pseudohalide ions and ferrocyanochrome *c*. The need for peroxidases apparently correlates with the common cellular production of hydrogen peroxide, a cytotoxic agent. In view of this it is not unusual to find peroxidases in many organisms, including animals, yeasts, fungi, plants, and bacteria. Initial NMR studies have emphasized HRP and CcP, probably due to the relative ease of isolating these two enzymes, their stability in solution, and, ultimately, the commercial availability of high purity preparations of HRP. All of the heme peroxidases so far identified possess molecular masses in the range of 30–150 kDa, making them a challenge for high resolution NMR spectroscopists.

2 PEROXIDASE CHEMISTRY

The general peroxidase mechanism was first formulated by Chance,⁶ and is shown below:

Figure 1 (a) Heme b structure and (b) coordination to the proximal histidine as it occurs in heme peroxidases. The widely used modified Fischer labeling scheme is used in (a). Several different labeling schemes are in use for histidine rings; shown in (b) is the IUPAC preferred scheme. In (b) the heme is shown edge-on as a heavy line. Many heme peroxidases contain heme b (e.g. horseradish peroxidase, cytochrome-*c* peroxidase, lignin peroxidase) or a simple derivative of heme b (e.g. lactoperoxidase, myeloperoxidase) at the enzyme active site

Briefly, it can be described as follows. In equation (1) the resting state enzyme, which for HRP and CcP is a high spin ferriheme protein (Figures 1 and 2), reacts with hydrogen peroxide to form the initial oxidized enzyme intermediate, variously termed compound I or compound ES, depending upon the peroxidase. Compound I is oxidized two equivalents above the resting state enzyme. Equation (1), generating compound I, can also be achieved when the peroxidase is allowed to react with organic peroxy acids of the type ROOH in place of hydrogen peroxide. In equation (2), compound I is reduced by one equivalent when it oxidizes one molecule of its substrate, generally represented here by AH_2 . The second enzyme intermediate generated in this step is called compound II, and is at an oxidation state elevated only one equivalent above the resting state enzyme. Finally, in equation (3), compound II is reduced to the resting state enzyme by oxidation of a second molecule of substrate.

Although equations (1)–(3) depict the general peroxidase enzymic cycle, the specific nature of the preferred substrate (AH_2) can vary from species to species. In particular, characterizing the interaction of peroxidases with their substrates is one of the problems that has recently attracted the attention of NMR spectroscopists. Other important problems addressed by early NMR studies included: (1) characterizing the heme active site; (2) making comprehensive proton assignments of hyperfine shifted resonances; (3) attempting proton assignments in the more crowded aromatic chemical shift region; (4) characterizing the enzyme intermediates, compound I and compound II; and (5) by these experiences defining the scope and limitations for modern NMR experiments on such medium-large sized paramagnetic macromolecules.

Figure 2 Peroxidase paramagnetism is demonstrated in this figure, which shows the electron configuration of heme iron ion d orbitals for various HRP and CcP intermediates. (a) Resting enzyme in the ferric high spin state. (b) Cyanide ligated, low spin enzyme derivative. (c) Compound I involves the $\text{Fe}^{4+}=\text{O}$ heme plus a second oxidizing equivalent localized on the porphyrin in HRP and on Trp191 in CcP. (d) Compound II, with the $\text{Fe}^{4+}=\text{O}$ heme

2.1 The Oxidized Enzyme Intermediates

How does a heme peroxidase store the oxidizing equivalents received during the initial hydrogen peroxide reaction step? This was one of the early questions facing peroxidase researchers, and a wide range of physical methods were applied to find the answer. In the case of HRP it is now generally accepted that HRP compound I consists of a ferryl heme iron ion ($\text{Fe}^{4+}=\text{O}$) and a porphyrin π cation radical^{2,3} (Figure 2). In the case of CcP it is generally accepted that CcP compound I is a ferryl heme iron ion ($\text{Fe}^{4+}=\text{O}$) and a free radical resulting from the oxidation of Trp191, an amino acid adjacent to both the heme and the (proximal) heme-coordinating His175.^{2,3}

For both HRP and CcP the second enzyme intermediate, compound II, is generally accepted as consisting of a ferryl heme iron ion ($\text{Fe}^{4+}=\text{O}$). However, at least in CcP there is evidence for the interconversion between two distinct compound II forms, that with the ferryl heme iron ion (CcPII_F) and that with a ferric heme and a free radical (CcPII_R). Other heme peroxidases exhibit similar characteristics for their individual oxidized intermediates, although the stability of peroxidase intermediates may vary widely.

Among the most intriguing properties of heme peroxidases is the comparatively stable heme iron +4 state of the oxidized intermediates. This is not a widely encountered formal oxidation state for iron, and it probably stimulated much of the early interest in these enzymes, raising such questions as how the enzyme structure stabilizes such a high oxidation state.

2.2 Effect of Heme Paramagnetism on NMR Spectra

In the ferriheme resting state and the two oxidized enzyme intermediates [equations (1)–(3)], heme peroxidases are paramagnetic by virtue of unpaired electrons in the heme iron ion d orbitals. A simple picture of the commonly encountered heme iron ion spin and oxidation states is given in Figure 2. Including the cyanide-ligated resting state enzyme, the commonly studied forms of peroxidases include three low

spin derivatives and one high spin (the native resting state enzyme) form, all of which are paramagnetic. This further emphasizes the need to consider briefly paramagnetic effects on NMR spectra.

Molecular paramagnetism due to unpaired electron density formally associated with the heme iron ion produces dramatic effects in NMR spectra as a result of the large local magnetic fields associated with these unpaired electrons.^{7–11} Unusually large, highly temperature dependent observed resonance shifts are found in paramagnetic molecules (Figure 3), and highly enhanced nuclear relaxation rates also occur as a consequence of nuclear magnetic moments coupling to the large unpaired-electron magnetic moments. The proton spectra shown for CcP compound I [Figure 3(a)], CcP [resting state, Figure 3(b)], and CcPCN [cyanide ligated, Figure 3(c)] illustrate the large shifts and linewidths that can occur. Electron–nuclear interactions and paramagnetic relaxation are treated elsewhere in this Encyclopedia, and it suffices here briefly to review the basic concepts as they are employed in interpreting NMR spectra of heme peroxidases.

2.2.1 The Hyperfine Shift^{7–11}

The observed resonance shift (δ_{obs}) for a given molecule in a paramagnetic peroxidase is the sum of two parts: the shift it would have in a corresponding purely diamagnetic form of the same peroxidase (δ_{dia}) and the shift caused by the unpaired electrons (δ_{para}) [equation (4)]. The paramagnetic

Figure 3 Proton NMR spectra of various forms of CcP: (a) Compound I, (b) resting state, and (c) the cyanide ligated enzyme (CcPCN). (a) and (b) were taken at 360 MHz in D_2O –buffer solutions, and share the same chemical shift scale. (c) was taken at 500 MHz in D_2O –buffer solution. Note the different chemical shift scales

shift (δ_{para}) has been referred to as the isotropic, or hyperfine shift and contains two terms, the contact shift (δ_{con}) and the pseudocontact, or dipolar shift (δ_{dip}) [equation (5)]. The contact shift is a consequence of metal–ligand covalency that results in delocalization of unpaired spin density from the heme iron ion onto its immediate ligands. This typically occurs by σ and/or π bonding. Previous work has shown that the extent of the contact shift is attenuated by the number of intervening bonds in the case of σ delocalization, whereas for π -type delocalization a significant effect may be found throughout the extent of the continuous π -bond network.

$$\delta_{\text{obs}} = \delta_{\text{dia}} + \delta_{\text{para}} \quad (4)$$

$$\delta_{\text{para}} = \delta_{\text{con}} + \delta_{\text{dip}} \quad (5)$$

The dipolar shift is a through-space interaction between the unpaired electron magnetic moments and the nuclear magnetic moments. It is distance dependent, falling off in intensity with the inverse third power of the direct distance between the unpaired electrons and the nucleus. In the highly delocalized heme iron ion ligation structure of peroxidase active sites (see Figure 1) there can be both iron centered dipolar shifts and ligand centered dipolar shifts, the latter deriving from delocalized unpaired electron spin density. The ligand centered dipolar shifts are typically the smaller of the two dipolar shifts. Detailed descriptions of the hyperfine shift equations have been presented.^{7–11}

2.2.2 Paramagnetic Relaxation Effects

Electron paramagnetic moments can also provide an efficient relaxation pathway for nuclear magnetic moments, thereby enhancing nuclear relaxation rates. Just as there are contact and dipolar (pseudocontact) contributions to the observed shift there are corresponding contributions to nuclear relaxation.^{7–11} Nuclei exhibiting strongly hyperfine shifted resonances also display unusually short longitudinal and transverse relaxation times. For paramagnetic proteins as large as the peroxidases, recovery of the nuclear magnetization of strongly hyperfine shifted resonances from inversion or saturation experiments is not characterized by a single exponential, thereby complicating interpretation of the term ' T_1 ' in these cases.¹¹ This is illustrated by the semilogarithmic plot of fractional magnetization recovery for nonselectively inverted CcP resonances shown in Figure 4. In the absence of cross relaxation, or spin diffusion, such a plot would be linear.^{11–13} Nonlinearity in graphs like this emphasizes the multiple exponential relaxation behavior, which is exacerbated by increasing paramagnetic protein size and/or increasing the spectrometer field strength.^{11–13}

2.2.3 Curie Spin Relaxation

Another phenomenon that affects the observability of hyperfine shifted resonances in large paramagnetic proteins such as peroxidases is the so-called Curie spin relaxation.^{8,14,15} It is the result of coupling the rotational angular momentum of a protein to its time independent paramagnetic moment. The effect is one of 'anomalous' line broadening, indicating that

Figure 4 The result of nonselective inversion recovery experiments for the heme 8-CH₃ resonance of CcPCN plotted semilogarithmically. The fractional recovered magnetization intensity is plotted against the interpulse delay time (τ , in the sequence 180– τ –90–acq). Nonlinear behavior indicates that relaxation is not governed by a single exponential process, but involves significant spin diffusion

it results in specific enhancement of nuclear transverse relaxation, and it increases as the second power of the magnetic field strength. The result is that larger proteins with larger paramagnetic moments (i.e. greater numbers of unpaired electrons) can exhibit severe line broadening, and it is common that such proteins may actually experience decreased resolution at higher fields.

3 PROTON ASSIGNMENTS

3.1 Earliest Peroxidase Studies

The earliest reports of peroxidase NMR spectra focused on HRP and turnip peroxidases.^{16–21} These studies provided spectra showing both strongly hyperfine shifted proton resonances and resonances in the broad overlapping envelope of protons between approximately –2 to 11 ppm. In this and other work reported prior to 1980, proton NMR was used to study processes involving the heme active site, primarily through monitoring hyperfine shifted resonances. These processes included pH dependence,^{16–19} ligand binding,^{16,18} formation and identification of the enzyme intermediates, compound I and compound II,²⁰ and calcium ion binding.²¹

Although illustrating the applicability of high-resolution NMR for studying fairly large (by NMR standards) paramagnetic proteins with large resonance linewidths, all of these early studies suffered from lack of specific resonance assignments. In part this was a result of the fact that chemical shift correlations, which are such helpful starting points for making resonance assignments in diamagnetic molecules, are not valid for strongly hyperfine shifted resonances. Also, at the time, few model systems had been developed that could provide any rationale for proposed assignments.

3.2 Definitive Proton Assignment Methods

The first unambiguous proton assignments were reported for resting state HRP, reduced HRP and HRP_{CN}.^{22–24} A single

proton belonging to the $N^{\pi}H$ of the heme-coordinating (see Figure 1) proximal histidine in each form was assigned. The results established the state of proximal histidine protonation for these various enzyme forms. This information was of functional importance for the reason that in the case of low spin HRPcN it indicated the validity of the idea that the enzyme stabilizes the low spin, oxidized intermediates by deprotonation of this histidine to form a histidinate ligand.

From such modest beginnings, many more specific assignments of hyperfine shifted proton resonances for CcP, HRP, lignin peroxidase, and, to a more limited extent, *Coprinus* peroxidase have been produced using a variety of techniques, including: (1) incorporation of specifically deuterated hemes,^{25–29} (2) one-dimensional NOE experiments,^{11,30,31} (3) two-dimensional spectroscopy,^{11,32–37} and (4) deuterium NMR.²⁹ Particularly impressive are the NOE-based assignments made in such large enzymes as lactoperoxidase-CN (mass 78 kDa)³⁸ and myeloperoxidase-CN (mass ~150 kDa).³⁹ Among the many conclusions that were drawn from these studies, perhaps the most important is the fact that paramagnetism subverts spin diffusion and makes it possible for NOE experiments to be successful on very large proteins, for which NOE experiments would not be successful if they were diamagnetic.

Two other conclusions of note concerning techniques for making assignments in peroxidases have been published. One concerns the use of NOE rise curves for deriving internuclear distances.⁴⁰ This work showed that NOE rise curves, such as that shown in Figure 5 for HRPcN are only linear over the initial 1–5 ms of the mixing period, and, consequently, only the slope in that region quantitatively relates to internuclear distances. Figure 5 shows that NOEs achieve maximum intensities at ~10–20 ms for strongly hyperfine shifted resonances in peroxidases, which stresses the short time intervals inherent in work with paramagnetic peroxidases. A second pair of studies concerns the utility of COSY-type two-dimensional experiments as tools for making hyperfine resonance assignments in peroxidases.^{41,42} The conclusion was reached that COSY displays complications such that cross peaks may be caused by sources other than the coherence transfer caused by scalar coupling. In particular it was shown that for two scalar coupled spins the cross correlation between internuclear dipole–dipole relaxation and the Curie spin relaxation is significant and often detected in COSY cross peaks.

3.3 Proton NMR Characterization of Oxidized Enzyme Intermediates

HRP compound I stores its oxidizing capacity centrally at the heme moiety as a porphyrin π cation radical/heme ferryl ($Fe^{4+}=O$) ion. This intermediate yields a comparatively rich proton NMR spectrum compared with HRP compound II, CcP compound I (see Figure 3), and CcP compound II, all of whose proton spectra are similarly composed of hard-to-interpret broad features^{20,43,44} Although original NMR data were interpreted as indicating that a high spin Fe^{4+} heme was present in HRP compound I, subsequent studies, including model studies of iron porphyrins, clearly established the low spin, ferryl heme that is now accepted as the compound I intermediate structure.

Figure 5 NOESY cross peak intensity versus mixing time for strongly coupled (geminal) proton pairs in HRPcN: $7H^{\alpha}-7H^{\alpha'}$ (∇); $4H^{\beta_c}-4H^{\beta_t}$ ($\blacktriangledown$); His170 $C^{\beta}H-C^{\beta}H'$ ($\square$); Arg38 $C^{\beta}H-C^{\beta}H'$ ($\bullet$); Arg38 $C^{\delta}H-C^{\delta}H'$ ($\circ$). The vertical scaling is identical for all data. The data are for the F_2 slices through the diagonal of the better resolved proton of the pair. (Reproduced by permission of the American Chemical Society from Sette et al.⁴⁰)

3.4 Peroxidase–Substrate Interactions

3.4.1 Horseradish Peroxidase

Peroxidases frequently catalyze oxidations of smaller substrates, typically organic or inorganic molecules. Among the many interesting questions left unresolved in this field are those concerning the mechanisms by which these oxidations take place. Thus, the thrust of much of the current research in this area is toward the elucidation of these mechanisms. Efforts have been made to understand the effects of substrate binding on the HRP and HRPcN hyperfine shift patterns and to locate the substrate binding site.^{36,45,46} Proton NMR results and chemical data agree that substrates such as benzhydroxamic acid bind at the heme periphery in the vicinity of the heme 8- CH_3 group (see Figure 1).

3.4.2 Cytochrome-*c* Peroxidase from *Saccharomyces cerevisiae*

Although CcP is capable of catalyzing oxidations of small molecules, on the basis of kinetic discrimination the functional role of this molecule is presumed to be that of a catalyst for the H_2O_2 oxidation of mitochondrial ferrocyanochrome *c*. Relative to equations (1)–(3), this means that following oxidation of CcP by H_2O_2 [equation (1)], CcP compound I oxidizes ferrocyanochrome *c* [equation (2)]. This is thought to occur through the formation of a noncovalent electron transfer complex. In equation (3), CcP compound II, which results from the first electron transfer step [equation (2)], oxidizes another reduced cytochrome *c* molecule, again via the formation of an electron transfer complex. As a result of their size and solubility, CcP/cytochrome *c* complexes have emerged as a paradigm for the multitude of protein–protein electron transfer complexes.

Mixtures of Ccp, independently with both ferricytochrome *c* and ferrocytochrome *c*, spontaneously form noncovalent complexes in low ionic strength solutions. Proton NMR has been used to study these complexes because NMR spectroscopy, among all of the spectroscopic techniques applied to this problem so far, is uniquely the most sensitive to complex formation.^{47–49} The capability to carry out these studies derives from the observation that ferricytochrome *c* hyperfine shifted proton resonances display significant complex-induced shifts (up to 2 ppm; Figure 6), although they are dependent upon the species of ferricytochrome *c*. The predominant complex stoichiometry found in solution is 1:1. Homonuclear proton NOESY two-dimensional spectra of these ~47 kDa complexes have facilitated hyperfine shift assignments, particularly when both proteins were in low spin magnetic states (i.e. CcPCN/ferricytochrome *c*).

A fundamental dynamic property of these noncovalent complexes, the lifetime of a yeast iso-1 ferricytochrome *c* molecule bound to the peroxidase, was first directly measured by one-dimensional magnetization transfer experiments (Figure 7).⁴⁷ This series of measurements was facilitated by the observation of simultaneous sets of resonances for free (in solution) and CcP-bound forms of yeast iso-1 ferricytochrome *c* in 1:2 mixtures of CcP/iso-1 ferricytochrome *c* and CcPCN/iso-1 ferricytochrome *c* (see Figure 6). Lifetimes between 1 and 4 ms were found for yeast iso-1 ferricytochrome *c* bound to either CcP or CcPCN, depending upon temperature. Perhaps more importantly, the lifetimes were found to be concentration dependent, indicating that exchange of a molecule of iso-1 ferricytochrome *c* from CcP (or CcPCN) is not controlled by

Figure 6 The high-frequency proton hyperfine shift region at 500 MHz of (a) yeast iso-1 ferricytochrome *c* alone in solution; (b) a 1:1 (mol/mol) mixture of CcP/yeast iso-1 ferricytochrome *c* in 10 mM potassium nitrate/D₂O; and (c) a 1:2 (mol/mol) mixture of CcP/yeast iso-1 ferricytochrome *c* in 10 mM potassium nitrate/D₂O. The iso-1 heme 8-methyl resonance appears at ~36 ppm in (a), and the heme 3-CH₃ resonance appears at ~32 ppm in (a). The linewidth increase and shift of the iso-1 resonances in (b) indicate noncovalent complex formation. In (c) the heme 3-CH₃ resonances of iso-1 free (in solution) and CcP bound are indicated by f and b, respectively. (Reproduced by permission of the American Chemical Society from Yi et al.⁴⁷)

Figure 7 (a) Stack plot of a complete inversion transfer experiment for a 1:2 mixture of CcP (0.25 mM) and yeast iso-1 ferricytochrome *c* carried out at 5 °C. The free-form yeast iso-1 ferricytochrome *c* heme 3-CH₃ resonance was inverted. (b) Relaxation profile of this inversion transfer experiment plotted as peak intensity vs. magnetization transfer mixing time for both the inverted resonance [heme 3-CH₃(f)] and its exchange coupled partner [heme 3-CH₃(b)]. The dashed and solid lines are calculated from Monte Carlo/least squares fitting to the exchange modified Bloch equations. The inset depicts the behavior of both peaks at early exchange times where chemical exchange dominates the intensity. (Reproduced by permission of the American Chemical Society from Yi et al.⁴⁷)

unimolecular dissociation. This has led to a reappraisal of the CcP mechanism of ferrocytochrome *c* oxidation.⁵⁰

4 MUTANT ENZYMES

Both HRP and CcP have been expressed in bacteria, and several mutants of each enzyme have been created for the purposes of NMR spectroscopy.^{36,51} Both studies are similar in reporting that single mutations of amino acids

have dramatic effects upon the heme electronic structure and active site physical structure. What is emerging from these studies, and unpublished data from this laboratory, is a picture of HRP and CcP having carefully balanced active sites, perhaps primed specifically for the hydrogen peroxide reaction. Amino acid mutations, even those employing closely related amino acids (e.g. Glu $\rightarrow$ Gln), and even those more than one molecular layer removed from the heme site, have very significant effects on the peroxidase active site chemistry and spectroscopy.⁵¹ Although mutations thus engender complicated spectral changes, making interpretations less than straightforward, it is anticipated that an increasing variety of peroxidase mutant enzymes will be studied by NMR in the future.

5 NUCLEI OTHER THAN THE PROTON

Although subject to less detailed interpretation than is possible for proton spectroscopy, there have been several reports of heteronuclear NMR studies of peroxidases. Typically these have involved isotope enrichment of a peroxidase heme ligand (e.g. CN⁻, SCN⁻). Detection of heme peroxidase derivatives using the heteronuclei ¹⁵N,⁵² ¹³C,⁵³ ¹⁷O,⁵⁴ ³⁵Cl,⁵⁵ ¹¹³Cd,⁵⁶ and ²H^{29,57} has been reported.

Both HRP and CcP genes are currently being expressed in bacteria, and this renders stable isotope enrichment of both enzymes feasible. This, in turn, would allow application of higher-dimensional NMR experiments. To date, no reports of general or selective stable isotope enrichment of these enzymes has appeared. Still, examples of these enriched enzymes and the accompanying higher-dimensional NMR experiments are likely to appear in the near future. These experiments should provide expanded insights into the general applicability of modern NMR methods to paramagnetic proteins of this size.

1 INTRODUCTION

Hemoglobin (Hb) carries O_2 from the lungs to the tissues and returns CO_2 from the tissues to the lungs. Human normal adult Hb (Hb A) is a tetrameric protein of molecular mass ~ 65 000 Da, consisting of two α chains of 141 amino acid residues each and two β chains of 146 amino acid residues each. Each chain contains a heme group, which is an iron complex of protoporphyrin IX. Each of the four heme groups of Hb binds a ligand. The oxygen binding curve of Hb A exhibits a sigmoidal shape, indicating that when one O_2 molecule is bound, succeeding O_2 molecules are bound more readily. Thus, the oxygenation of Hb A is a cooperative process. The dependence of the oxygen affinity of Hb A on pH, which is known as the Bohr effect, is an important physiological property, resulting in a greater ease of unloading of O_2 when the muscles are acidic and more O_2 is needed. In addition to hydrogen ions, chloride, carbon dioxide, inorganic phosphate, 2,3-diphosphoglycerate (2,3-DPG), and inositol hexaphosphate (IHP) also influence the binding of O_2 or CO to Hb A. These compounds are known as heterotropic or allosteric effectors of Hb A. For a detailed description of Hb, see Dickerson and Geis.¹

Under physiological conditions, the heme iron atoms of Hb are in the ferrous state [Fe(II)]. When O_2 is bound, each of the heme iron atoms of oxyhemoglobin (Hb O_2) is in the low spin, diamagnetic ferrous state. In the absence of oxygen, each of the heme iron atoms of deoxy-Hb contains four unpaired electrons, and is in the high spin, paramagnetic ferrous state. Other forms of Hb, such as ferric Hb (methemoglobin, met-Hb), cyanomet-Hb, and azidomet-Hb, also contain unpaired electrons in their heme iron atoms, and are thus paramagnetic. Hyperfine interactions are produced between the unpaired electrons of the heme iron atoms and the protons in the porphyrins, as well as the protons of the nearby amino acid residues, i.e. in the vicinity of the heme groups of Hb. The π electrons in the porphyrin molecule can produce ring current shifts in the resonances from the protons in the porphyrins and the protons of the nearby amino acid residues. Because of these interactions, the proton chemical shift of an Hb molecule covers a very large spectral range, from about 20 ppm below the frequency of H_2O to about 90 ppm above the frequency of H_2O , depending on the spin state of the iron atoms and the nature of ligands attached to the heme groups (Figure 1).

Proton NMR spectroscopy has been shown to be a very powerful technique for investigating the structure–function

Figure 1 Proton NMR spectra (300 MHz) of 1.4 mM human normal adult hemoglobin (Hb A) in 0.1 M phosphate at pH 7.1 in H_2O at $29^\circ C$ over the spectral range from -30 to $+90$ ppm from H_2O and 2,2-dimethyl-2-silapentane-5-sulfonate (DSS): (a) oxy-Hb A and (b) deoxy-Hb A ($\times 100$ means that the spectrum is expanded 100 times from the original spectrum). relationship in Hb. It can monitor the binding of O_2 to the α and β chains of Hb A, and the tertiary and quaternary structural changes of the Hb molecule as a function of oxygenation under different experimental conditions. It has provided unique information about the structural changes associated with the cooperative oxygenation of Hb, the structural characteristics of partially ligated species of Hb (i.e. Hb with one, two, and three bound O_2 molecules), and the molecular basis for the Bohr effect of Hb A. These are among the central problems in contemporary Hb research. For details, see Ho and co-workers,^{2–8} and the references therein. In this article, we give representative results from our 1H NMR investigations of Hb.

2 METHODS

2.1 Preparation of Hb Samples for 1H NMR Studies

Hb A has been isolated from human blood samples obtained from the local blood bank. Human abnormal Hbs have been isolated from blood samples of individuals whose blood contains such mutant Hbs, provided for us by colleagues around the world. Now we are also able to produce human abnormal Hbs by site directed mutagenesis using our *Escherichia coli* expression system.^{9a} The Hb samples for 1H NMR studies can be prepared in either H_2O or D_2O media. Deoxy-, oxy-, or carbonmonoxy-Hb samples for 1H NMR studies are prepared by procedures developed in our laboratory.^{2,3,7}

2.2 Proton NMR Techniques

Any Fourier transform NMR spectrometer manufactured in the 1980s by major instrument companies is capable of obtaining ^1H NMR spectra of Hb. With a modern 7 T high-resolution NMR spectrometer operating at 300 MHz for ^1H , a satisfactory ^1H NMR spectrum (with a signal-to-noise ratio of ~ 20 or better) of a 0.3–0.5 ml sample of ~ 1 mM Hb contained in a 5 mm sample tube can be obtained in a few minutes.

To obtain ^1H NMR spectra of Hb samples in H_2O media, solvent suppression techniques are needed to reduce the dynamic range of the solvent protons in the sample. We have found that the jump-and-return pulse sequence developed by Plateau et al.¹⁰ is very useful for obtaining ^1H resonances of Hb over the spectral range from 8 ppm below the frequency of H_2O to 22 ppm above the frequency of H_2O . To obtain very high-frequency hyperfine shifted exchangeable proton resonances from 50 to 90 ppm above the frequency of H_2O , we have recently developed a general method of selective excitation for shaped pulses and pulse sequences.^{8a} When the Hb samples are prepared in D_2O media, standard pulse sequences available in a Fourier transform NMR spectrometer are capable of obtaining excellent ^1H NMR spectra of the Hb samples. We have found that the pulse sequence, developed by Hochmann and Kellerhals,¹¹ which selects the fastest relaxing resonances for observing while suppressing the slow relaxing ones (i.e. the diamagnetic proton resonances), is quite useful for obtaining the hyperfine shifted proton resonances of some forms of Hb over the spectral region from 5 to 30 ppm above the frequency of HDO.

The optimal magnetic field strength for ^1H NMR studies of Hb depends on both the spin state of the heme iron atoms of Hb and the nature of the measurement. For the hyperfine shifted proton resonances of deoxy-Hb and met-Hb, the linewidths increase with the square of the resonance frequency, whereas the resolution between the resonances only increases linearly with frequency.¹² Thus, there is a magnetic field at which both optimal sensitivity and optimal resolution can be obtained. For the hyperfine shifted proton resonances of deoxy-Hb, the optimal magnetic field appears to be around 7.0 T (or 300 MHz). Due to the chemical exchange contribution to the spin–spin relaxation, the linewidth of the C-2 proton resonances of histidyl residues of Hb also increases with the square of the resonance frequency.¹³ There is no improvement in resolution in going from 300 to 600 MHz, and, thus, the His C-2 proton resonances of Hb can be readily obtained in a 300 MHz NMR spectrometer.¹³ On the other hand, we have found that for diamagnetic proton resonances such as the exchangeable and ring-current shifted proton resonances, a 500 or 600 MHz NMR instrument gives better sensitivity and resolution than a 300 MHz spectrometer.

A commonly used proton chemical shift standard for ^1H NMR studies of proteins in aqueous solution is the proton resonance of the methyl group of the sodium salt of 2,2-dimethyl-2-silapentane-5-sulfonate (DSS). This resonance is +4.73 ppm above the frequency of the proton resonance of H_2O at 29 °C. Because all of our Hb samples contain H_2O (in the case of samples in D_2O , there is residual HDO present), it is convenient to take the proton resonance of H_2O in each sample as the internal reference. By taking account of the variation of the proton chemical shift of H_2O with temperature, we can always refer the proton chemical shift of H_2O to that

of DSS. At the recommendation of IUPAC,¹⁴ the chemical shift scale has been defined as positive in the region of the NMR spectrum at a higher frequency (lower field) than the resonance of a standard, and negative at a lower frequency. It should be noted that in our earlier publications we used the negative sign to indicate a chemical shift that was higher in frequency than that of the reference.

3 RESULTS

3.1 Proton NMR Spectra of Hb

The ^1H NMR spectrum of Hb can be divided into spectral regions that have been used to monitor structural (i.e. spectral) changes associated with the ligation of Hb A and the variation of the His C-2 proton resonances of Hb A as a function of pH. For details, see Figure 1 and Ho and co-workers.^{2–7}

The greatest intensity of resonances in the spectra of oxy- and deoxy-Hb lies in the region between +5 and –5 ppm from HDO. Resonances in the most crowded spectral region, –1 to –5 ppm from HDO, arise from the protons of the large number of CH_2 and CH_3 groups in the aliphatic amino acid residues of oxy- and deoxy-Hb A. Resonances in the region +2 to +6 ppm from HDO arise from the aromatic amino acid residues of oxy- and deoxy-Hb A. The region from +2.8 to +3.8 ppm contains the C-2 protons of the histidyl residues, whereas the region from +1.8 to +2.8 ppm contains resonances from the C-4 protons of the histidyl residues as well as aromatic proton resonances from tryptophans, tyrosines, and phenylalanines. The C-2 proton resonances of the histidyl residues have been used to investigate the molecular basis of the Bohr effect of Hb A.^{3–7}

Resonances from oxy-Hb A are limited to the region between +8.5 and –8 ppm. Resonances from +5 to +8.5 ppm from H_2O arise from the exchangeable proton resonances of oxy-Hb A. They are excellent markers for the subunit interfaces and the oxy quaternary structure.¹⁵ Resonances in the region –5 to –8 ppm from H_2O arise from the ring-current shifted protons due to those protons located above and/or below the aromatic amino acid residues as well as the porphyrins of oxy-Hb A. They are very sensitive markers for the tertiary structure of the heme pocket^{16–18} and have also been used to monitor the binding of O_2 to Hb A.^{8b}

Resonances from the paramagnetic deoxy-Hb extend from +80 to –20 ppm. Resonances in the region +50 to +80 ppm from H_2O arise from the hyperfine shifted N_δH exchangeable protons of the proximal histidyl residues of the α and β chains of deoxy-Hb A. They can be used to monitor the binding of O_2 to the α and β hemes of Hb A.^{8b,19} Resonances in the region +5 to +20 ppm from H_2O of deoxy-Hb A are due to two sources. First, they arise from the protons of the heme groups and their nearby amino acid residues due to the hyperfine interactions between these protons and the unpaired electrons of the high spin ferrous heme iron atoms of deoxy-Hb A. They have been used to monitor the binding of O_2 to the α and β chains of deoxy-Hb A as well as the structural changes associated with the oxygenation of Hb.^{20–22} Second, they arise from the exchangeable protons due to intra- and intermolecular hydrogen bonds in deoxy-Hb A. They have been used to monitor the changes in tertiary and quaternary structures as

a function of the oxygenation of Hb A.^{15,20} Resonances in the region -6 to -20 ppm from H₂O arise from the ring-current shifted protons and the protons of the heme groups and their nearby amino acid residues due to the hyperfine interactions between these protons and the unpaired electrons of the high spin ferrous heme iron atoms of deoxy-Hb A.

3.2 Assignments of Proton Resonances of Hb

For proteins the size of Hb, a commonly used method for assigning proton resonances to specific amino acid residues is to compare the ¹H NMR spectra of normal and appropriate mutant or chemically modified molecules. This approach is shown in Figure 2, where the aromatic proton resonance region of the ¹H NMR spectrum of deoxy-Hb A is compared with those of mutant Hb Deer Lodge ($\beta 2\text{His} \rightarrow \text{Arg}$) and of enzymatically modified Hb (des-His($\beta 146$), i.e. $\beta 146\text{His}$ deleted). As a result of the replacement by arginine, a non-aromatic amino acid, of the histidyl residue at position $\beta 2$, two resonances at $+3.32$ and $+2.30$ ppm from HDO are missing from the ¹H NMR spectrum of deoxy-Hb Deer Lodge as compared to that of deoxy-Hb A, both in 0.1 M bis(2-hydroxyethyl)iminotris(hydroxymethyl)methane (Bis-Tris) buffer in D₂O at pH 6.30. There are no other observable differences between these two spectra. Thus, these two resonances can be assigned to the two protons of $\beta 2\text{His}$ of deoxy-Hb A, the one at $+3.32$ ppm to the C-2 proton and the other at

$+2.30$ ppm to the C-4 proton of the histidyl residue. Similarly, by comparing the ¹H NMR spectrum of deoxy-Hb A to that of deoxy-des-His($\beta 146$)Hb, both in 0.1 M Bis-Tris in D₂O at pH 6.30, the resonances at $+3.80$ and $+2.76$ ppm from HDO can be assigned to the C-2 and C-4 protons of $\beta 146\text{His}$ of deoxy-Hb A, respectively.

The above approach is weakened when a single mutation or chemical modification produces significant conformational alterations in other regions of the protein molecule. Such effects can produce changes in the ¹H NMR spectrum which make spectral assignments ambiguous. There are a number of ways to remedy this resonance assignment problem. First, one can use several mutant Hbs with a change in the same amino acid residue to clarify or confirm the assignment. This approach is becoming very feasible with the availability of a suitable expression system which can be used to produce any desired mutant Hbs.^{9b,c} Second, one can use independent techniques to confirm the resonance assignment based on the mutant Hbs. One-dimensional NOE and 2D NMR techniques can be combined with X-ray structural information to make and confirm resonance assignments of Hb A.^{18,23} Over the years, more than 70 proton resonances of Hb A have been assigned. The assignments of these resonances are tabulated in our recent reviews.^{2,4}

3.3 The Cooperative Oxygenation of Hb

Two models have been offered to explain the sigmoidal nature of the oxygen binding curve of Hb A, one based on a concerted mechanism, proposed by Monod et al.,²⁴ and the other based on a sequential mechanism, proposed by Koshland et al.²⁵ The concerted mechanism postulates that, in the absence of ligand, there is an equilibrium between the low affinity deoxy conformation (T form) and the high affinity oxy conformation (R form), and that the transition from the T form to the R form is a concerted process, i.e. no intermediate or hybrid conformation RT exists. On the other hand, the sequential mechanism does not assume the existence of an equilibrium between the T and R forms in the absence of ligand, but postulates that the transition from the T to the R form is induced by the ligand binding, i.e. a sequential process. The intermediate species, RT, plays a very important role in the sequential mechanism. Both mechanisms can account for the oxygen binding curve of Hb A very well, in spite of the conceptual differences between them. This is not surprising in that, because of the highly cooperative oxygenation process, there are very few partially oxygenated species, i.e. Hb(O₂)₁, Hb(O₂)₂, and Hb(O₂)₃, present during the oxygenation process. However, it is only through a detailed characterization of the structural and functional properties of these partially oxygenated species that one can gain a full understanding of the structure–function relationships in Hb A.

Proton NMR studies of Hb during the past 35 years have provided new insights into the cooperative oxygenation of Hb A. Our approach has been twofold. First, we have monitored structural (spectral) markers of Hb A as a function of oxygenation under different experimental conditions. From these studies, we have gained information regarding the binding of O₂ to the α and β chains of Hb A and the structural changes associated with the cooperative oxygenation

Figure 2 Aromatic proton resonances (250 MHz) of deoxy-Hb A, deoxy-Hb Deer Lodge ($\beta 2\text{His} \rightarrow \text{Arg}$), and deoxy-des-His($\beta 146$ deleted) in 0.1 M Bis-Tris in D₂O at pH 6.3 and 27 °C. Assignment of the proton resonances of the C-2 and C-4 protons of histidyl residues at $\beta 2$ and $\beta 146$ of deoxy-Hb A. (Reproduced by permission of Academic Press from Ho and Russu³)

of Hb A.^{20–22} Second, we have used naturally occurring valency hybrid mutant Hbs (such as Hb M Milwaukee)^{26,27} and synthetic cross-linked mixed valency hybrid Hbs^{28,29} as models for partially oxygenated species. For recent reviews on this subject, see Ho and co-workers.^{2,4}

3.3.1 Binding of O₂ to the α and β Chains of Hb and Associated Structural Changes

The ferrous hyperfine shifted proton resonances of deoxy-Hb A in the spectral region from +5 to +20 ppm from HDO and the ferrous hyperfine shifted N₈H exchangeable proton resonances in the region from +55 to +75 ppm from H₂O

provide unique markers for investigating the binding of O₂ to the α and β chains of Hb A. Since these are hyperfine shifted resonances, they disappear from the high-frequency region of the spectrum (or return to their normal diamagnetic resonance region) when the Hb molecule is converted to the diamagnetic oxy state on O₂ binding.

Figure 3 shows a representative series of the hyperfine shifted proton resonances over the spectral range +6 to +20 ppm from HDO as a function of oxygenation in D₂O at pH ~6.4 in the absence and presence of organic phosphates.²¹ The resonances at about +12 and +18 ppm from HDO have been assigned to the α and β chains of deoxy-Hb A, respectively. Figure 4 gives a comparison of the relative intensities of the

Figure 3 Proton NMR studies (250 MHz) of the oxygenation of Hb A in 0.1 M Bis-Tris in D₂O at 27 °C: (a) 18% Hb at pH 6.44; (b) difference spectra of 18% Hb A at pH 6.44; (c) 13% Hb A plus 35 mM 2,3-DPG at pH 6.34; (d) difference spectra of 13% Hb A plus 35 mM 2,3-DPG at pH 6.34; (e) 11.5% Hb A plus 10 mM IHP at pH 6.42; and (f) difference spectra of 11.5% Hb A plus 10 mM IHP at pH 6.42. It should be noted that pD = pH + 0.4. (Reproduced by permission of the American Chemical Society from Viggiano et al.²¹)

Figure 4 A comparison of the relative intensities of the α -heme resonance at 12 ppm (Δ) and the β -heme resonance at 18 ppm ($\circ$) with the percentage of fully deoxy-Hb tetramers (—) as a function of oxygenation: (a) in 0.1 M Bis-Tris at pH 6.44; (b) in 0.1 M Bis-Tris plus 35 mM 2,3-DPG at pH 6.34; and (c) in 0.1 M Bis-Tris plus 10 mM IHP at pH 6.42. The fraction of fully deoxy-Hb tetramers was calculated from the data of Tyuma et al.³⁰ (Reproduced by permission of the American Chemical Society from Viggiano et al.²¹)

α -heme resonance at +12 ppm and the β -heme resonance at +18 ppm with the percentage of fully deoxy-Hb tetramers as a function of O_2 saturation in the absence and presence of organic phosphates. In the absence of organic phosphates, the areas of the +12 and +18 ppm resonances decrease at the same rate, i.e. the α and β chains of Hb A have similar affinity for O_2 [Figure 4(a)]. In the presence of organic phosphates, the area of the α peak at +12 ppm follows the behavior of the fully deoxy-Hb A populations, while the area of the +18 ppm β peak remains significantly larger than that of the +12 ppm α peak on oxygenation [Figure 4(b) and (c)]. This means that the presence of even one O_2 molecule in the Hb tetramer is enough to cause a decrease in the area of the +12 ppm α resonance, but not the +18 ppm β resonance. In the presence of IHP, the α chains have a much higher O_2 affinity than the β chains. As a first approximation, we can assume that, at low O_2 saturations, both the singly and doubly oxygenated species all have O_2 molecules bound on the α chains. The behavior of the +18 ppm β chain resonance, which is sensitive to both ligation and structural changes, shows that the number of modified β chains is less than the number of modified α chains.^{21,22} The relative intensity of the +12 ppm α chain resonance follows the population of the fully deoxy-Hb tetramers, suggesting that all of the oxygenated species either have O_2 bound to the α chains or have some structural modifications in the unligated α chains. Thus, our 1H NMR results suggest that a strong cooperativity must exist in the oxygenation of the α chains and that the oxygenation of one α chain affects the ligand affinity of the other unligated α chain within a tetrameric Hb molecule.^{21,22} These results suggest that there are more than two affinity states in the Hb molecule on ligand binding. Thus, the structural changes at partial O_2 saturations in the presence of organic phosphates cannot be concerted as required by two-state allosteric models, even if extended to take into account the differences in affinity between the α and β chains as proposed by Ogata and McConnell.³¹ These conclusions based on the behavior of the resonances at +12 and +18 ppm are also supported by experiments making use of other resonances.^{2,20}

What relationship do the conclusions based on these *in vitro* experiments have to the situation *in vivo*? We have monitored the intensities of the hyperfine shifted N_8H exchangeable proton resonances of the proximal histidyl residues of the α and β chains of deoxy-Hb at about +59 and +71 ppm from

H_2O , respectively, as a function of O_2 saturation by using a soft 121 pulse sequence to suppress the H_2O signal in a fresh hemolysate at pH 6.6.¹⁹ From the variation of the intensities of the resonances at about +59 and +71 ppm, we have concluded that the α chains of Hb A have a higher affinity for O_2 than the β chains. This is in agreement with the measurement of the relative intensities of the hyperfine shifted proton resonances at +12 and +18 ppm in the presence of organic phosphates. More recently, we have improved our pulse sequences for solvent suppression,⁸ and our new pulse sequences allow us to monitor the binding of O_2 to Hb A inside intact red blood cells. Our results indicate that in fresh human red blood cells the α chains of Hb A have a higher affinity for O_2 than the β chains,^{8b} in agreement with the results obtained from Hb A in solution in the presence of organic phosphates.

3.3.2 Models for Partially Ligated Species of Hb

The structural information about the partially ligated species of Hb A inferred from the previous section is indirect, i.e. it does not provide direct structural characteristics for the partially oxygenated species, $Hb(O_2)_1$, $Hb(O_2)_2$, and $Hb(O_2)_3$, formed during the oxygenation process. This is due to the fact that the oxygenation of Hb A is a highly cooperative process. Thus, there are very few partially oxygenated species present. There is also a rapid dimer exchange in the tetrameric Hb molecule, which makes it difficult to isolate intermediate species.

In this section, we describe our second approach for gaining structural information about partially ligated Hb species, using Hb M Milwaukee ($\beta 67Val \rightarrow Glu$, $\alpha_2\beta_2^+$) and cross-linked asymmetric mixed valency hybrid Hbs. As a result of the amino acid substitution $\beta 67Val \rightarrow Glu$, the two β chains of Hb M Milwaukee are in the high spin ferric state.³² Thus, in deoxy-Hb M Milwaukee, the heme iron atoms in the α and β chains have different paramagnetic properties. The hyperfine shifted proton resonances of the high spin ferrous state of deoxy-Hb A occur in the spectral range from +5 to +20 ppm from H_2O , whereas those of the high spin ferric state occur in the spectral range from +10 to +90 ppm from H_2O . Using these ferric hyperfine shifted proton resonances of Hb M Milwaukee, it is possible not only to explore the structures of fully deoxygenated and fully oxygenated Hb M Milwaukee but also to observe the structural alterations at the ligand binding site of one type of subunit (β^+ -hemes), which are associated with the binding of O_2 to the neighboring subunits (α -hemes). Thus, these 1H NMR measurements can provide a direct probe of the structural manifestation of the 'heme-heme' interactions in Hb M Milwaukee.^{26,27}

Figure 5 shows the variation of the ferric hyperfine shifted proton resonances of the β^+ -hemes of Hb M Milwaukee as a function of oxygenation in 0.1 M Bis-Tris buffer at pH 6.6 and 30°C. By analyzing the variation of the ferric hyperfine shifted proton resonances of Hb M Milwaukee as a function of oxygenation, we have concluded that the ferric hyperfine shifted proton resonance spectrum of singly oxygenated Hb M Milwaukee cannot be obtained as an average of the corresponding spectra of fully deoxygenated and fully oxygenated Hb M Milwaukee.^{26,27} These 1H NMR results indicate that during the course of oxygenation, unligated binding sites may adopt intermediate as well as deoxy-like and oxy-like conformations. This conclusion is not consistent

Figure 5 Ferric hyperfine shifted proton resonances (250 MHz) of the abnormal β chains of 15% Hb M Milwaukee ($\beta 67\text{Val} \rightarrow \text{Glu}$, $\alpha_2\beta_2^+$) as a function of oxygenation in 0.1 M Bis-Tris in D_2O at pH 6.6 and 30°C . The proton chemical shifts are referenced to HDO. The range of fractional oxygenation (y) was based on $P_{50} = 5$ torr or $P_{50} = 10$ torr. (Reproduced by permission of the American Chemical Society from Fung et al.²⁷)

with the prediction of two-structure allosteric descriptions for the cooperative oxygenation of Hb. Thus, by implication, two-structure allosteric models cannot satisfactorily explain the structural changes of Hb A associated with the oxygenation process.

The exchange of two dissociated dimers of Hb can be prevented by introducing a cross-linking (XL) reagent, such as bis(3,5-dibromosalicyl)fumarate, which cross-links the Lys82 residues of the two β subunits.³³ This technique has enabled

us to prepare various asymmetric cyanomet mixed valency hybrid Hbs, i.e. with one cyanomet heme in either an α or β subunit, or with two cyanomet hemes one in an α and one in a β chain within a tetrameric Hb molecule. Cyanomet heme has been used as a model for ligated heme in Hb research for a long time. Thus, we have prepared $(\alpha^{+\text{CN}}\beta)_A(\alpha\beta)_C\text{XL}$ and $(\alpha\beta^{+\text{CN}})_A(\alpha\beta)_C\text{XL}$ to serve as models for singly ligated species, and $(\alpha^{+\text{CN}}\beta^{+\text{CN}})_A(\alpha\beta)_C\text{XL}$ and $(\alpha\beta^{+\text{CN}})_A(\alpha^{+\text{CN}}\beta)_C\text{XL}$ to serve as models for doubly ligated

Figure 6 Proton NMR spectra (600 MHz) of cross-linked mixed valency asymmetric hybrid hemoglobins in 0.1 M phosphate at pH 6.8 and 21 °C in deoxy and CO forms: (a) Hb(α^{+CN}β)_A(αβ)_CXL and (b) Hb(αβ^{+CN})_A(αβ)_CXL models for singly ligated species. (Reproduced by permission of the American Chemical Society from Miura and Ho²⁸)

species, the first one for the partially ligated α₁β₁ dimer and the second one for the partially ligated α₁β₂ dimer.

Figure 6 shows the 600 MHz ¹H NMR spectra of (α^{+CN}β)_A(αβ)_CXL and (αβ^{+CN})_A(αβ)_CXL, the models for singly ligated Hbs. The sharp resonances shown in Figure 6(a)(i) and (b)(i) are due primarily to the low spin ferric hyperfine shifted proton resonances associated with the cyanomet chains, because the hyperfine shifted proton resonances due to the high spin ferrous chains are too broad (> 1200 Hz) to be detectable under our measuring conditions.¹² The binding of CO to (α^{+CN}β)_A(αβ)_CXL, the model for a ligated α chain, produces significant spectral changes in the low spin ferric hyperfine shifted proton resonances of the α^{+CN} chain, as shown in Figure 6(a)(i). On the other hand, the spectral changes of (αβ^{+CN})_A(αβ)_CXL, the model for a ligated β chain, in going from the deoxy to the CO form, are quite minor, as shown in Figure 6(b)(i), i.e. the resonances from the deoxy form are already in the positions found in the oxy-like quaternary structure.

Figure 6(a)(ii) and (b)(ii) give the proton resonances of (α^{+CN}β)_A(αβ)_CXL and (αβ^{+CN})_A(αβ)_CXL in H₂O in both

the deoxy and CO forms over the spectral region from +7 to +11 ppm from H₂O. These resonances are mainly the hyperfine shifted proton resonances associated with the low spin cyanomet chains and the exchangeable proton resonances. Again, the hyperfine shifted proton resonances due to the high spin ferrous chains are too broad to be observable under our measuring conditions.¹² The resonance at about +9.2 ppm in these spectra shows approximately half the intensity of the corresponding resonance in deoxy-Hb A or cross-linked Hb A.²⁸ This resonance disappears on going from the deoxy to the ligated form, and has been assigned to the intersubunit hydrogen bond between α42Tyr and β99Asp in the α₁β₂ subunit interface, a deoxy quaternary structural marker.^{15,28} The 50% reduction of the resonance at +9.2 ppm might suggest the equal coexistence of the two quaternary structures. However, the resonances from the cyanomet β chain as seen in Figure 6(b)(i) indicate that all are in the ligated form. Therefore, the results imply that at least one intermediate quaternary structure must be taken into account, in which about half of the hydrogen bonds responsible for the resonance at +9.2 ppm are altered.

We have also obtained similar 600 MHz ^1H NMR spectra of $(\alpha^{+\text{CN}}\beta^{+\text{CN}})_A(\alpha\beta)_{\text{CXL}}$ and $(\alpha\beta^{+\text{CN}})_A(\alpha^{+\text{CN}}\beta)_{\text{CXL}}$ in both deoxy and CO forms.²⁸ Overall, the 600 MHz ^1H NMR spectra of these two valency hybrid Hbs are quite similar to each other. There are small spectral changes in these two hybrid Hbs in going from the deoxy to the CO form. The most obvious difference between the cross-linked hybrid Hbs with two cyanomet chains and those with one cyanomet chain is the absence of the characteristic deoxy quaternary spectral marker at about +9.2 ppm from H_2O in the former hybrid Hbs. This suggests that the hybrid Hbs with two cyanomet chains per $\alpha\beta$ tetramer do not have the usual deoxy quaternary structure as manifested by the intersubunit hydrogen bond between $\alpha 42\text{Tyr}$ and $\beta 99\text{Asp}$.

Thus, the structural changes during the ligation process are not concerted, and two-structure allosteric models are not sufficient to describe fully the cooperation oxygenation of Hb A. It should be mentioned that spectral changes observed for the high spin ferric hyperfine shifted proton resonances of the β chains in Hb M Milwaukee on oxygenation of its α chains as described earlier in this section are consistent with the results on cross-linked asymmetric mixed valency hybrid Hbs with one cyanomet chain.

Ackers and co-workers³⁴ have carried out extensive thermodynamic measurements of cooperative free energies of quaternary assembly of Hb A, mutant Hbs, and Hbs with metal substituted porphyrins. They have concluded that singly ligated species such as $[(\alpha^{+\text{CN}}\beta)(\alpha\beta)]$ and $[(\alpha\beta^{+\text{CN}})(\alpha\beta)]$ and a doubly ligated species, $[(\alpha^{+\text{CN}}\beta^{+\text{CN}})(\alpha\beta)]$, have identical cooperative free energy and that they all belong to the T quaternary structure. These conclusions are inconsistent with our results as discussed in this section. Further work is needed to resolve these discrepancies.

3.4 The Molecular Basis for the Bohr Effect of Hb A

The Bohr effect is the change of the oxygen affinity of Hb A with pH. The alkaline Bohr effect results in the release of protons from the Hb molecule during the transition from the deoxy to the oxy state at a pH above 6.0. The acid Bohr effect results in the absorption of protons upon oxygenation below pH 6.0. Besides the alkaline and acid Bohr effects of Hb A, there is an additional Bohr effect that originates from the oxygen-linked interactions of the Hb molecule with solvent anions. It has been shown that the release of about half of the Bohr protons is due to a difference in chloride binding to the oxy and deoxy forms of Hb A.³⁵ Besides the α -amino terminal, the imidazole groups from the histidyl residues, because of their pK_a values in the physiologically relevant range, are the most likely amino acid residues of Hb for which changes in pK_a values on oxygenation and on anion binding could contribute significantly to the Bohr effect.

The involvement of the surface histidyl residues in the Bohr effect originates from the changes in their electrostatic environments accompanying the change in the conformation of the Hb molecule on ligation and/or on anion binding. Several histidyl residues of Hb A, in particular $\beta 2\text{His}$ and $\beta 146\text{His}$, have been proposed, on the basis of X-ray diffraction data and the results on mutant and chemically modified Hbs, to play an important role in the Bohr effect. As shown in Figures 1 and 2, the C-2 proton resonances of the histidyl residues of Hb A are

Figure 7 Alkaline Bohr effect of Hb A in D_2O in 0.1 M HEPES at 29°C , and the contributions of $\beta 2\text{His}$ and $\beta 146\text{His}$ as calculated from the pK_a values determined by ^1H NMR spectroscopy. ---, measured Bohr effect; ..., $\beta 2\text{His}$ contribution; ---, $\beta 146\text{His}$ contribution; —, sum of the contributions from $\beta 2\text{His}$ and $\beta 146\text{His}$. (Reproduced by permission of the American Chemical Society from Busch et al.⁷)

well separated from those of other proton resonances. There are 11–13 histidyl residues per Hb dimer (or 22–26 histidyl residues per Hb tetramer) that can be resolved and titrated individually by ^1H NMR spectroscopy in both deoxy and CO forms under a wide range of experimental conditions.^{3–7} The pK_a values are determined by a nonlinear least-squares fit of the ^1H chemical shift as a function of $[\text{H}^+]$. From the pK_a values and the experimental values of the partial pressure of O_2 at 50% saturation obtained for a wide range of pH values, the hydrogen ions released per Hb molecule can be calculated under the assumption that the same 22–26 histidyl residues are observed in the deoxy and in the CO forms.

Figure 7 shows the measured Bohr effect of Hb A in chloride-free 0.1 M 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES) at 29°C and the protons calculated to be contributed by $\beta 2\text{His}$ and $\beta 146\text{His}$. The summation of the contributions of $\beta 2\text{His}$ and $\beta 146\text{His}$ to the Bohr effect does not correspond to the total measured Bohr effect. It is clear that there are many more amino acid residues involved in the Bohr effect than $\beta 2\text{His}$ and $\beta 146\text{His}$.

We have also used ^1H NMR spectroscopy to investigate the molecular mechanism of the Bohr effect in the presence of allosteric effectors such as chloride, inorganic phosphate, or 2,3-DPG.^{6,7,36,37} The interactions of chloride and inorganic phosphate ions with the Hb molecule result in lowering the pK_a values of several surface histidyl residues and/or changes in the shapes of the H^+ binding curves. These results suggest that long-range electrostatic interactions between individual ionizable sites in Hb A could play an important role in the molecular mechanisms of the anion Bohr effect. The addition of an equimolar concentration of 2,3-DPG to the Hb A solution affects several His C-2 proton resonances in both the deoxy and CO forms. The largest effect is observed for the $\beta 2\text{His}$ and originates from an increase in the pK_a value of this histidyl residue in the presence of 2,3-DPG [Figure 8(a)]. In 0.1 M HEPES, $\beta 2\text{His}$ captures about 0.46 protons per Hb tetramer upon oxygenation at pH 6.0, and therefore contributes to the acid Bohr effect under these conditions. At pH 7.0, $\beta 2\text{His}$ absorbs about 0.17 protons per Hb tetramer, and thus makes a negative contribution to the

Figure 8 Contributions of (a) $\beta 2\text{His}$ and (b) $\beta 146\text{His}$ residues to the Bohr effect of Hb A under different experimental conditions. (Reproduced by permission of Elsevier Science Publishers from Busch and Ho⁶)

overall alkaline Bohr effect. As seen in Figure 8(a), the curves for the 0.1 M Bis-Tris/Tris and 0.1 M Bis-Tris + 0.18 M NaCl conditions nearly superimpose, with $\beta 2\text{His}$ still capturing up to 0.20 protons per Hb tetramer upon ligation at about pH 6.5, thus still opposing the macroscopically observed Bohr effect. In the presence of 0.1 M phosphate, $\beta 2\text{His}$ releases up to 0.15 protons per Hb tetramer, making a small, but positive, contribution to the alkaline Bohr effect. The $\beta 2\text{His}$ residue releases up to 0.56 protons per Hb tetramer upon ligation in 0.1 M Bis-Tris + 2,3-DPG, a significant contribution to the alkaline Bohr effect.

Figure 8(b) shows the contributions of $\beta 146\text{His}$ to the Bohr effect. The contributions of this amino acid residue to the Bohr effect remain positive under the conditions studied, but the magnitude of its contribution can be significantly altered by different experimental conditions. Using pH 7.4 as a reference pH, $\beta 146\text{His}$ contributes 0.49 protons per Hb tetramer to the Bohr effect in 0.1 M HEPES, 0.1 M phosphate, 0.85 protons per Hb tetramer, in 0.2 M phosphate + 0.2 M NaCl, 0.93 protons per Hb tetramer, in 0.1 M Bis-Tris + 2,3-DPG, 1.18 protons per Hb tetramer, and 1.24 protons per Hb tetramer in 0.1 M Bis-Tris. Our results also indicate that $\beta 146\text{His}$ is not a site for the binding of chloride or inorganic phosphate, yet these anions can significantly increase the contribution of this amino acid residue to the Bohr effect.

The examples of $\beta 2\text{His}$ and $\beta 146\text{His}$ clearly illustrate that the microscopic behavior of a specific group in Hb

is determined by its site-specific chemical and electrostatic environments, defined by both the Hb structure and by the environment in which the Hb molecule resides. As a result, depending on solvent conditions, the individual behavior of a group could either contribute to the behavior seen macroscopically for the system, or oppose that behavior. Thus, the detailed molecular mechanism for the Bohr effect of Hb A is not unique, but is dependent on the nature of the solvent, both by direct interactions and by long-range electrostatic and/or conformational perturbations.^{5–7}

In order to gain insights into the nature of the Bohr effect inside red blood cells (RBCs), we have compared the C-2 proton resonances of histidyl residues of purified Hb A, lysed RBCs, and intact RBCs.⁴ The resonances from lysed cells are much better resolved than those of the intact cells. As a first step, we have carried out a preliminary investigation of the C-2 proton resonances of the histidyl residues of HbCO A in lysed cells and compared them to those of purified HbCO A under similar conditions. The pH titration curves of several C-2 proton resonances of histidyl residues in the lysed cells are very similar to those of HbCO A.⁴ These preliminary results suggest that the study of lysed RBCs can provide useful information about the Bohr effect inside intact RBCs.

4 CONCLUSIONS

In this article we have given a few examples of the use of ^1H NMR to study the structure–function relationship in Hb A. Our results show that the structural changes associated with the cooperative oxygenation process are not concerted, and that within the deoxy quaternary state some cooperativity must be present during the oxygenation process. These results are not consistent with two-structure allosteric descriptions of the oxygenation of hemoglobin. Our ^1H NMR studies of the Bohr effect of Hb A illustrate that the microscopic behavior of a specific amino acid residue in Hb A is determined by the Hb structure and by the environment in which the Hb molecule resides. The variable role of a given amino acid residue under different solvent conditions has been demonstrated for $\beta 2\text{His}$ and $\beta 146\text{His}$, and implies that the molecular basis for the Bohr effect of Hb A is not unique and depends on solvent conditions. Our ^1H NMR results clearly indicate that Hb is a very interactive molecule, i.e. perturbations at one site can be propagated to other parts of the molecule.

The Hb problem is certainly not yet solved. There are more exciting discoveries to be made by researchers in the coming years. With the recent success in creating a suitable expression system which can be used to produce any desired mutant hemoglobins, we have a unique opportunity to gain new insights into the molecular basis of signal transfer from a ligated subunit to its unligated partners within a tetrameric Hb molecule and to assign additional amino acid residues which contribute to the Bohr effect of Hb A. Hb is an excellent model for investigating the molecular basis of the properties of allosteric proteins and of signaling phenomena at the atomic level. Thus, NMR, in combination with appropriate engineered Hbs, offers an excellent approach to investigating these problems.

1 INTRODUCTION

FeS proteins are defined as proteins containing sulfide ions bridging two or more iron ions.^{1–4} We consider here those proteins having cysteines as the only protein ligands to associate with iron (Figure 1). We mention also proteins containing a single iron coordinated to four cysteines (rubredoxins). FeS proteins have been investigated through NMR since the start of investigations into paramagnetic systems in solution^{5,6} (see *Electron–Nuclear Hyperfine Interactions*; *Electron–Nuclear Multiple Resonance Spectroscopy*, *Nonheme Iron Proteins*, and *Paramagnetic Relaxation in Solution*). Most of these molecules have short electronic relaxation times, and therefore have relatively long nuclear relaxation times, which make them suitable for high-resolution NMR studies. Short electronic relaxation times are due to one or more of the following reasons:^{7,8} (i) the various iron ions experience sizeable antiferromagnetic coupling, which causes a decrease in magnetic susceptibility—therefore, the nuclear relaxation times are longer than expected in the absence of magnetic coupling; (ii) polymetallic systems involving more than two metals may have new relaxation mechanisms available with respect to the uncoupled systems; and (iii) when there are two ions with different valence, one will have shorter electronic relaxation times—in the present case, iron(II) has shorter electronic relaxation times than iron(III); when magnetic coupling occurs, the electronic relaxation times of iron(III) will become shorter, approaching those of iron(II).

The observation of the NMR signals of the cysteine ligand nuclei provides information on the nature of the iron ion to which the cysteine is bound and on the extent of magnetic coupling. Recently, NOE (see *Nuclear Overhauser Effect*) and 2D studies have permitted the sequence specific assignments of the coordinated cysteines in a number of cases.^{9–19} NMR, together with magnetic Mössbauer spectroscopy, thus permits the determination of the cysteine ligands bound to a given iron ion. Owing to the progress in spectrometer design together with the optimization of the spectral parameters, the attainment of 2D and 3D spectra (see *Biological Macromolecules: Structure Determination in Solution* and *Multidimensional*

Figure 1 Iron coordination in rubredoxin (1-Fe) and in the most common iron–sulfur clusters (2-Fe, 3-Fe, 4-Fe, and 6-Fe) in proteins. The overall charges, related to the accessible oxidation states, are also shown

Spectroscopy: Concepts) is now possible on these paramagnetic systems, and, notwithstanding the fact that the presence of the paramagnetic center still complicates the life of the spectroscopist, the resolution of the first 3D structures of proteins of the type discussed here is now at hand.²⁰

The following article deals first with the NMR parameters of the metal coordinated cysteines and nearby residues, and then with the more classical NMR investigations.

2 NMR AND HYPERFINE COUPLING IN VARIOUS FeS PROTEINS

The hyperfine coupling, as usual, contains contact, pseudocontact, and ligand centered contributions (see *Electron–Nuclear Hyperfine Interactions* and *Electron–Nuclear Multiple Resonance Spectroscopy*). We refer here only to contact contributions, which presumably are dominant; extension to the other contributions, if needed, is easy.

2.1 $[\text{Fe}_2\text{S}_2]^{2+/1+}$ -Containing Proteins

2.1.1 Oxidized $[\text{Fe}_2\text{S}_2]^{2+}$ Forms

The ^1H NMR spectrum shows a broad absorption around 40 ppm to high frequency which contains unresolved cysteine $\beta\text{-CH}_2$ signals (Figure 2).²¹ The observability of the signal is due to the reduced paramagnetism, which results from the strong antiferromagnetic coupling. By using the formalism $\hat{\mathcal{H}} = J\hat{\mathbf{S}}_1 \cdot \hat{\mathbf{S}}_2$, the results are accounted for with a J value of about 300 cm^{-1} .⁴ The ground state is diamagnetic. With increasing temperature, the hyperfine shifts increase because

Figure 2 (a) Proton NMR spectrum (303 K, 200 MHz) of oxidized $[\text{Fe}_2\text{S}_2]^{2+}$ ferredoxin from spinach. (b) Calculated temperature dependence of the hyperfine shifts of $\beta\text{-CH}_2$ protons under antiferromagnetic coupling ($J = 290 \text{ cm}^{-1}$) between the two iron ions, and experimental temperature dependence (inset)⁴

excited paramagnetic levels are more and more populated. This behavior is said to be of anti-Curie type. In the absence of magnetic coupling, as in the case of the oxidized protein rubredoxin, containing only iron(III), the cysteine $\beta\text{-CH}_2$ protons are indeed broadened beyond detection.

2.1.2 Reduced $[\text{Fe}_2\text{S}_2]^+$ Forms

The antiferromagnetic coupling between an iron(III) and an iron(II) ion gives a ground state with $S = \frac{1}{2}$. The ^1H NMR spectrum shows four signals between 100 and 140 ppm at high frequency (downfield), and several signals closer to the diamagnetic region (Figure 3).²² The former have a temperature dependence of the Curie type, whereas the latter are of the anti-Curie type. It soon became evident, on the basis of the available theory,²³ that the signals with anti-Curie behavior belonged to the iron(II) domain, and the others to the iron(III) domain. This is because iron(III) with $S = \frac{5}{2}$ will force iron(II) with $S = 2$ to behave in a different way with respect to what would have happened in the absence of antiferromagnetic coupling. NMR, therefore, has shown that one of the two iron ions is more easily reduced, or is the only reducible ion (actually, one iron could be reduced at, for example, 90% and the other at 10%, the equilibrium between the two species being fast). In a number of proteins, two cysteines (e.g. Cys41 and Cys46 in *S. platensis* ferredoxin) are found to be close to each other and two protons can give inter-residue NOE (see *Nuclear Overhauser Effect*). Such

Figure 3 (a) Proton NMR spectrum (297 K, 300 MHz) of reduced $[\text{Fe}_2\text{S}_2]^+$ ferredoxin from spinach. (b) Experimental temperature dependence of the hyperfine shifts; signals a–d arise from $\beta\text{-CH}_2$ protons of cysteines coordinated to iron(III), while signals f–i arise from $\beta\text{-CH}_2$ protons of cysteines coordinated to iron(II)²²

cysteines have been identified and recognized to be ligands of iron(II).^{9,10} This biochemical information could be obtained only through NMR.

2.2 $[\text{Fe}_3\text{S}_4]^{1+/0}$ -Containing Proteins

In the oxidized state the ground state is $S = \frac{1}{2}$. At the moment, two signals shifted well to high frequency have been observed which belong to one cysteine, plus two signals still at high frequency.^{19,24,25} The sequence specific assignment of these signals in *D. gigas* ferredoxin II has been obtained recently¹⁹ using the methodology described in Section 2.3. According to the present theory, we may have $S = \frac{5}{2}$ of one Fe^{3+} antiferromagnetically coupled to $S = 2$ of the other two Fe^{3+} ions. In other words, the magnetic coupling constants would be different among the three iron ions. The two signals of the cysteine bound to the $S = \frac{5}{2}$ Fe^{3+} are very much to high frequency, and four signals should be either at high frequency but close to the diamagnetic region, or at low frequency. The former signals should be of the Curie type.

The reduced form has $S = 2$, and no cysteine $\beta\text{-CH}_2$ signal has ever been observed. Probably, due to the large paramagnetism and unfavorable electronic relaxation times, the $\beta\text{-CH}_2$ signals are broadened beyond detection.

2.3 $[\text{Fe}_4\text{S}_4]^{3+}$ -Containing Proteins

This cluster is present in oxidized HiPIPs. Formally, it contains one iron(II) and three iron(III). Actually, each cluster

Figure 4 (a) Proton NMR spectrum (298 K, 600 MHz) of oxidized $[\text{Fe}_4\text{S}_4]^{3+}$ HiPIP II from *E. halophila*. (b) Experimental temperature dependence of the hyperfine shifts⁴

comprises a mixed valence pair with oxidation state +2.5 and two iron(III) ions. In the mixed valence pair, one electron is delocalized over two iron ions. Such a pair has a subspin larger than the iron(III) pair. The ground state is $S = \frac{1}{2}$. Therefore, the protons sensing the mixed valence pair are very much to high frequency, whereas the protons sensing the iron(III) pair are to low frequency.^{12,13} The temperature dependence is shown in Figure 4. The occurrence of these valences is due to inequivalent antiferromagnetic couplings between pairs of iron ions and to electron delocalization within the mixed valence pair. The valence distribution within the cluster is determined by the protein frame. In the case of the HiPIP iso-II from *E. halophila* the residues bound to the mixed valence pair are Cys39 and Cys71, and those bound to the iron(III) ions are Cys42 and Cys55.¹³ Of course, there are six different ways to delocalize one electron over two vertices of a cubane. It is believed that in another five HiPIPs investigated, a rapid equilibrium between two species differing for the valence distribution within the protein frame occurs.^{11–16,26,27}

The sequence specific assignment is obtained by saturating each cysteine proton and observing NOE on nearby protons. Then, through NOESY (see *NOESY*), COSY (see *COSY Two-Dimensional Experiments*), or TOCSY (see *TOCSY in ROESY and ROESY in TOCSY*) maps, the signals of the latter protons are recognized to belong to a given residue. If the X-ray structure (or a reliable structural model) is available, then the above connectivities are enough to perform the sequence specific assignment.^{11–16}

Figure 5 Plot of the hyperfine shifts of cysteine $\beta\text{-CH}_2$ protons (left) and α carbons (right-hand scale) for $[\text{Fe}_4\text{S}_4]^{2+}$ proteins, as a function of the Fe-S-C-H and Fe-S-C-C dihedral angles θ . Data refer to the following: oxidized *C. acidu urici* (●) and *C. pasteurianum* (○) ferredoxins; reduced *C. vinosum* (△) and *E. halophila* iso-II (▽) HiPIPs; and oxidized *C. acidu urici* (□, α carbon) ferredoxin¹⁸

2.4 $[\text{Fe}_4\text{S}_4]^{2+}$ -Containing Proteins

Such polymetallic centers are present in reduced HiPIPs and oxidized ferredoxins. The iron ions have an oxidation state of +2.5. The ground state is diamagnetic, but appreciable paramagnetism arises from the population of the excited states. The shifts are all to high frequency and have an anti-Curie type of behavior.^{21,28} The sequence specific assignment around the metal cluster is available for a number of HiPIPs^{12,14} and two ferredoxins.¹⁸ The system has been found ideal for investigating the angular dependence of the cysteine nuclei (protons and carbons) contact shifts.¹⁸ It is found that such shifts depend on the M-S-C-X ($X = {}^1\text{H}, {}^{13}\text{C}$) dihedral angle according to the following relationship:

$$\delta = a \sin^2 \theta + b \cos \theta + c \quad (1)$$

where $a = 10.9$, $b = -2.3$, and $c = 4.0$ ppm.⁴ In Figure 5 the relative plot is reported. Such dependence has been attributed to a predominant involvement of the π orbital of sulfur in the spin transmission.

2.5 $[\text{Fe}_4\text{S}_4]^+$ -Containing Proteins

This cluster is present in reduced ferredoxins. The electronic properties have been again explained on the basis of a mixed valence pair ($S = \frac{9}{2}$) and two iron(II) ions ($S = 4$). The ground state is $S = \frac{1}{2}$, although in model compounds ground states with higher spins have been found. The overall picture is less clear than in the case of oxidized HiPIPs, because the antiferromagnetic coupling between pairs of iron ions is smaller and the excited levels are closer. All the $\beta\text{-CH}_2$ protons experience high frequency shifts, although the temperature dependences of the shifts are of both Curie and anti-Curie types.²⁹

Several ferredoxins contain two Fe_4S_4 clusters. In this case they experience the equilibrium shown in Scheme 1. The equilibria between oxidized, reduced and intermediate species are slow, so that each of the three species gives a distinct pattern of NMR signals. Furthermore, saturation transfer between each pair of species is observed. The two

Scheme 1

Figure 6 2D EXSY spectrum (293 K, 600 MHz) of 50% reduced *C. pasteurianum* ferredoxin. The two EXSY cross peaks from each of the most hyperfine shifted signals, belonging to the reduced form, correspond to the intermediate and oxidized forms²⁹

species at intermediate oxidation states are in fast equilibrium; therefore, they give averaged signals whose position indicates the predominance of one species. The EXSY spectrum (see *Chemical Exchange Effects on Spectra* and *Two-Dimensional Methods of Monitoring Exchange*) is shown in Figure 6.²⁹

The sequence specific assignment of the bound cysteines is available for the proteins from *C. pasteurianum* and *C. acidithiobacillus*.¹⁸

3 STRUCTURAL INFORMATION ON THE DIAMAGNETIC PART

From the above presentation it appears that FeS proteins are suitable examples with which to pursue the advancement of NMR in paramagnetic molecules, because the electronic relaxation times can be short and the paramagnetism small. Markley and others have pioneered the assignment of the protein part through ¹H, ¹³C, and ¹⁵N spectroscopies.^{10,30,31}

Most of these studies are typical diamagnetic studies. Carbon-13 and ¹⁵N HETCOR (see *Heteronuclear Shift Correlation Spectroscopy*) studies are available on natural and ¹⁵N-labeled proteins, respectively.³² In the latter case, 3D spectra (¹⁵N-¹H-¹H) are now available.²⁰ In the case of the reduced HiPIP (Fe₄S₄²⁺) from *C. vinosum*, 79 out of 85 residues have been assigned,³³ whereas in the case of ferredoxin (Fe₂S₂⁺) from *Anabaena*, 81 out of 99 residues have been assigned and information on the secondary structure is available.³⁰ The difficulty remains that when a residue is close to the cluster often the sequence specific connectivities necessary for the assignment of that residue are lost. The Florence laboratory has successfully explored the possibility of overcoming this difficulty. The assignment of 71 residues out of 73 has now been reached for the recombinant HiPIP iso-I from *E. halophila*, and now the 3D structure is being refined based on 1000 NOE constraints.²⁰ Molecular dynamics approaches involving open shell metal ions have been developed.^{13,34} The future of the NMR investigation of FeS proteins is now very promising, and biochemical information is now obtainable on the recently prepared mutants and on mixed metal proteins.

Biographical Sketches

Ivano Bertini. *b* 1940. Italian Doctor, 1964; free docent (1969), lecturer (1965) and Professor of Chemistry (1975) at the University of Florence, Italy. More than 300 publications; with C. Luchinat the book (1986), *NMR of Paramagnetic Molecules in Biological Systems*, Benjamin/Cummings, Menlo Park, CA, and with L. Banci and C. Luchinat the book (1991), *Nuclear and Electron Relaxation*, VCH, Germany. Research interests include the structure and dynamics of paramagnetic metalloproteins, nuclear relaxation, electron relaxation, protein chemistry, and environmental biotechnology.

Claudio Luchinat. *b* 1952. Italian Doctor, 1976, University of Florence. Introduced to NMR by I. Bertini. Faculty positions at Florence University, 1978–1986. Full Professor of Chemistry at Bologna University 1986–present. Nasini Award in Inorganic Chemistry in 1989. Approx. 200 publications. Research fields: NMR of paramagnetic species, theory of electron and nuclear relaxation, magnetic coupled systems, biological applications of NMR, bioinorganic, biophysical, environmental chemistry.

1 INTRODUCTION

The use of metal containing compounds in medicine and health applications has been practiced for several thousand years.¹ The Egyptians used copper to sterilize water in 3000 BC and the Chinese were using gold in a variety of medicines 3500 years ago. In fact, the first modern chemotherapeutic agent was an organoarsenic compound (Erlisch's arsphenamine), although modern pharmaceuticals are dominated by organic compounds. The success of cisplatin as an anticancer drug has largely stimulated the modern use of metal compounds for therapy and diagnosis. Beside platinum, clinically useful metal compounds include gold in antiarthritic agents, lithium for manic depression, antimony in antileishmaniasis, bismuth in antiulcer drugs, gadolinium (Gd^{3+}) as a magnetic resonance imaging contrast agent and technetium ($^{99\text{m}}\text{Tc}$) as radio-diagnostic agents (Table 1).^{1–4} Not only do inorganic compounds extend the range of drugs available, but they are also successful in treating some diseases where organic compounds are not.

Both the metal and the bound ligands determine the biological activity of metallodrugs, not just the metal. The active species may not be that which is administered or tested in vitro, and it may be biotransformed by ligand substitution and/or redox reactions before it reaches the target sites. It is important to investigate both kinetic (ligand-exchange dynamics, mechanism and pathway) and thermodynamic aspects of the reactivity of a metal compound since biological systems are rarely at thermodynamic equilibrium. Modern multinuclear and multidimensional NMR spectroscopy is a very powerful method for investigation of the speciation of metal complexes in solution, and to a lesser extent in the solid-state, and is applicable for studies of the interaction of metal compounds with biomolecules under physiologically relevant conditions.

Although almost all of the available NMR techniques have been used for studying metallodrugs, ^1H NMR spectroscopy

continues to be the most widely used method for monitoring the behavior of ligands and biomolecules. Other spin 1/2 nuclei such as ^{13}C , ^{15}N , ^{31}P and ^{195}Pt , and weak quadrupolar nuclei (e.g., ^6Li , ^7Li , ^{27}Al and ^{51}V , Table 2) have also quite often been used and ^7Li will be discussed in a later section. Most medicinally relevant metals are quadrupolar nuclei. Antimony, bismuth and gold have a limited number of useful NMR isotopes. This situation may improve at very high fields (e.g., 14.1 T and over), which are expected to dramatically sharpen the central transition ($m = 1/2$ to $-1/2$) of half-integer quadrupolar nuclei such as ^{27}Al ($I = 5/2$), ^{45}Sc ($I = 7/2$) and ^{71}Ga ($I = 3/2$), Table 2.⁵ Other candidates include biologically important elements, e.g., ^{25}Mg , ^{43}Ca and ^{67}Zn . In the limit of slow isotopic molecular motion (e.g., macromolecules, $\omega\tau_c \gg 1$), the linewidth ($\Delta\nu_{1/2}$) of the central transition ($m = 1/2$ to $-1/2$) decreases with increasing magnetic field:

$$\Delta\nu_{1/2} = k \left[\frac{\chi^2}{\tau_c \nu_0^2} \right] \quad (1)$$

where χ is the quadrupolar coupling constant ($\chi = e^2qQ/h$), τ_c is the correlation time for fluctuations in the electric field gradient at the nucleus and ν_0 is the resonance frequency which is proportional to the magnetic field. Decreasing temperature and increasing viscosity also give rise to a decrease in linewidths.⁶ In these quadrupolar systems, the apparent shift is field-dependent, in contrast to $I = 1/2$ nuclei. The second-order dynamic frequency shift is given by:^{7,8}

$$\Delta\delta_d = \delta_{\text{obs}} - \delta_{\text{iso}} \left(m = \frac{1}{2} \text{ to } -\frac{1}{2} \right) = k \left(\frac{\chi^2}{\nu_0^2} \right) \quad (2)$$

The chemical shift of ^{71}Ga in ovotransferrin, for example, is -103 ppm at 11.7 T but -57 ppm at 17.6 T.^{5b}

This article provides examples of the application of NMR spectroscopy to the speciation of metallopharmaceuticals in solution and in the solid-state including biofluids and cells, and complexation to biomolecules (nucleic acids, peptides and proteins). Since the topic is vast, we focus on platinum anticancer, gold antiarthritic, lithium and bismuth antiulcer drugs. The reader is referred to related papers in this encyclopedia and elsewhere.⁹

2 PLATINUM (AND OTHER METALLO) ANTICANCER DRUGS

The accidental observation of the inhibition of bacterial division by *cis*-diamminedichloroplatinum(II) (cisplatin, *cis*- $\text{Pt}(\text{NH}_3)_2\text{Cl}_2$ or *cis*-DDP) in 1965 by Rosenberg led to the antiproliferative effects of this compound being applied to therapy of human tumours.^{10–12} Today cisplatin is among the most active and widely used anticancer drugs, together with the second-generation drug carboplatin $\text{Pt}(\text{NH}_3)_2(\text{CBDCA}-\text{O},\text{O}')$, where CBDCA is cyclobutane-1,1-dicarboxylate). Two new platinum compounds nedaplatin and oxaliplatin have recently been approved for clinical use in Japan and France, respectively (Scheme 1). Ru^{3+} compounds and the organometallic complex titanocene dichloride also have promising anticancer activities.

2 BIOCHEMICAL APPLICATIONS

Table 1 Some metallodrugs and diagnostic agents

Compounds	Product	Use	Transformation events	Biological targets
Li_2CO_3	Camcolit	Manic depression	Widely distributed in body	Enzymes in inositol phosphate pathways
$\text{Na}_2[\text{Fe}^{\text{II}}(\text{NO})(\text{CN})_5]$	Nipride	Hypotensive crisis (vasodilator)	Release of CN^- , reaction with thiols	Release of NO to guanylate cyclase
Zn^{II} pyridithione	Omadine	Antimicrobial (antidandruff)		Skin
$^{67}\text{Ga}^{\text{III}}$ citrate	Neoscan	Diagnostic radio-imaging	Transferrin	Tumors and inflammatory lesions
$^{99\text{m}}\text{Tc}^{\text{V}}_{-\text{D,L-HM-PAO}^{\text{a}}}$	Ceretec	Diagnostic radio-imaging	Ligand exchange?	Brain
$^{99\text{m}}\text{Tc}^{\text{I}}[(\text{C}\equiv\text{N-R})_6]^+{}^{\text{b}}$	Cardiolite	Diagnostic radio-imaging	Potassium channel?	Myocytes (heart)
Ag^{I} sulfadiazine	Flamazine	Antibacterial (burn wounds)	Protein binding	Enzymes (e.g., phosphomannose isomerase), cell walls?
$\text{Na}[\text{Sb}^{\text{V}}\text{stibogluconate}]$	Pentostam	Antileishmanial	Unknown	Parasites in liver
BaSO_4	Baridol	X-ray contrast agent	None (insoluble in water)	Passage through GI tract
$[\text{Gd}^{\text{III}}(\text{DTPA})](\text{meglumine})_2$	Magnevist	MRI contrast agent	None	Extracellular water
$[\text{Gd}^{\text{III}}(\text{DOTA})]^-$	Dotarem	MRI contrast agent	None	Extracellular water
<i>cis</i> - $[\text{Pt}^{\text{II}}\text{Cl}_2(\text{NH}_3)_2]$	Cisplatin	Anticancer	Hydrolysis, L-Met adducts and GSH	DNA
$\text{Pt}^{\text{II}}[(\text{CBDCA})(\text{NH}_3)_2]^{\text{c}}$	Carboplatin	Anticancer	L-Met adducts, ring open and release of CBDCA, and GSH	DNA
Au^{I} thiomalate	Myocrisin	Antiartthritic drug	Thiol exchange, MT, albumin (Cys^{34}), oxidation to Au^{III} ?	Lysosomes (aurosomes), thiol group of proteins
$\text{Et}_3\text{P Au}^{\text{I}}(\text{acetylthioglucose})$	Auranofin	Oral antiarthritic drug	Phosphine oxidation, Au^{I} to Au^{III} ?	Lysosomes (aurosomes), thiol group of proteins
Colloidal Bi^{III} citrate	De-Nol	Antiulcer and antimicrobial	GSH, MT and transferrin?	Block Fe^{III} uptake? enzymes in <i>Helicobacter pylori</i> ?
Ranitidine Bi^{III} citrate	Pylorid	Antiulcer and antimicrobial	GSH, MT and transferrin?	Block Fe^{III} uptake? enzymes in <i>Helicobacter pylori</i> ?

^aHM-PAO is hexamethyl propyleneamine oxime.

^b $\text{C}\equiv\text{N-R}$ represents 2-methoxyisobutylisocyanide.

^cCBDCA is 1,1-dicarboxycyclobutane.

Table 2 Useful NMR properties of selected elements

Nucleus	Spin	Natural abundance (%)	Quadrupole moment (10^{-28} m)	Receptivity/ ^{13}C	NMR Frequency (100 MHz ^1H)
^6Li	1	7.42	-6.4×10^{-4}	3.58	14.717
^7Li	3/2	92.58	-3.7×10^{-2}	1.54×10^3	38.864
^{13}C	1/2	1.108		1	25.145
^{14}N	1	99.63	1.6×10^{-2}	5.7	7.224
^{15}N	1/2	0.37		2.2×10^{-2}	10.136
^{25}Mg	5/2	10.00	0.1999	1.54	6.126
^{27}Al	5/2	100	0.140	1.17×10^3	26.077
^{31}P	1/2	100		3.77×10^2	40.480
^{51}V	7/2	99.76	-5.2×10^{-2}	2.16×10^3	26.350
^{67}Zn	5/2	4.11	0.150	0.665	6.252
^{69}Ga	3/2	60.40	0.168	2.38×10^2	24.040
^{71}Ga	3/2	39.60	0.106	3.19×10^2	30.495
^{109}Ag	1/2	48.18		0.276	4.653
^{195}Pt	1/2	33.8		19.1	21.414

Scheme 1 Structures of clinically used platinum compounds. The carbons marked with asterisks are chiral carbons (Oxaliplatin contains *R,R*-1,2-diaminocyclohexane)

2.1 ^{195}Pt , ^{15}N NMR and Inverse $[^1\text{H}$, $^{15}\text{N}]$ NMR Spectroscopy

In addition to ^1H NMR, the use of ^{15}N and ^{195}Pt NMR spectroscopy has made an important impact, along with other biophysical techniques, in the understanding of the mode of action of platinum anticancer drugs. This includes the detection of intermediates arising during the hydrolysis process and in reactions with either DNA or amino acids (peptides and proteins), and metabolites in body fluids.⁹ ^{195}Pt ($I = 1/2$) is a reasonably sensitive nucleus for NMR detection with natural abundance of 33.8% (Table 2) and a receptivity relative to ^1H of 3.4×10^{-3} . The spin-relaxation time for ^{195}Pt is usually in the range of 0.014–8.3 s, with most values less than 2 s.¹³ The short relaxation times (T_1) are attributed to efficient relaxation via the chemical shift anisotropy (CSA) and spin-rotation (SR) contributions. The advantage of the increased sensitivity achievable at high magnetic field for ^{195}Pt is offset by the increase in linewidths due to CSA relaxation ($\propto B_0^2 \tau_c$). Similarly, ^{195}Pt satellites in either ^1H or ^{15}N spectra of Pt^{2+} complexes are often broadened beyond detection at high fields,

again due to CSA relaxation of ^{195}Pt , which excludes the use of $[^1\text{H}$, $^{195}\text{Pt}]$ inverse detection to enhance the sensitivity of detection. The low detection limit (ca. 10 mM) precludes detection of natural abundance ^{195}Pt signals under biologically relevant conditions (e.g., in body fluids), but can be enhanced by isotopic enrichment of ^{195}Pt to >95%. A previous report has shown that DNA platination at millimolar concentrations can readily be studied with ^{195}Pt enrichment and both mono- and bi-functional guanine adducts were detected (Scheme 2 and Figure 1).¹⁴ The rate-determining step for initial binding of cisplatin was found to be hydrolysis of the first chloride and similarly the rate-determining step for closure of the monofunctional species to form bifunctional adducts was found to be hydrolysis of the second chloride.

The chemical shift range of ^{195}Pt is very large (15 000 ppm and usually in the range from –6000 to 9000 ppm). Ready differentiation between Pt^{2+} and Pt^{4+} is usually possible. The former (Pt^{2+}) tends to have chemical shifts at the higher field while the latter resonates in the low-field end of the range. The ^{195}Pt chemical shift in monomeric compounds is usually highly sensitive to the nature of bound donor atoms and can

Scheme 2 Structures of cisplatin aqua-chloro intermediate, mono- and bi-functional DNA adducts

Figure 1 Time-dependent ^{195}Pt NMR spectra of the reaction between cisplatin and chicken erythrocyte DNA at 37 °C in 3 mM NaCl, 1 mM NaH_2PO_4 . (Adapted with permission from Ref.¹⁴)

Table 3 ^{195}Pt chemical shifts of *cis*-Pt complexes with different donor atoms

<i>Cis</i> -Pt complexes	$\delta(^{195}\text{Pt})$ range ^a	References
<i>cis</i> -[Pt(NH ₃) ₂ Cl ₂]	−2048 to −2168 ^b	14,15
<i>cis</i> -[Pt(NH ₃) ₂ Cl(O)]	−1806 to −1841	16
<i>cis</i> -[Pt(NH ₃) ₂ Cl(N)]	−2295 to −2369	14,18,19
<i>cis</i> -[Pt(NH ₃) ₂ (O) ₂]	−1570 to −1730	15–17
<i>cis</i> -[Pt(NH ₃) ₂ (N) ₂]	−2440 to −2661	14,16,17
<i>cis</i> -[Pt(NH ₃) ₂ (N)(O)]	−2058 to −2147	16,17
<i>cis</i> -[Pt(NH ₃) ₂ (N)(S)]	−2800 to −3218	20,21
<i>cis</i> -[Pt(NH ₃) ₂ (O)(S)]	−2618 to −2800	20,21
<i>cis</i> -[Pt(NH ₃) ₂ (S) ₂]	−3200 to −3685	20,21

^aReference to Na₂PtCl₆.^bSlightly varies in different solvents, $\delta(^{195}\text{Pt}) = -2048$ (DMF), -2097 (DMSO) and -2149 (water).

be used as a diagnostic tool to distinguish various types of ligand binding to platinum (Table 3).^{15–21} Moreover, the ^{195}Pt chemical shifts are very sensitive to complex geometry, e.g., geometrical isomers and diastereomers, and can be utilized in the detection of different intermediates formed during the reaction of platinum complexes with biomolecules. ^{195}Pt NMR shifts for conformers of bis-guanine derivatives differing only by rotation about the Pt–N7 bond can vary by as much as 13 ppm (see Scheme 2).²² Sometimes even isotopomers are distinguishable: the ^{195}Pt isotope shift difference for Pt–³⁵Cl and Pt–³⁷Cl is 0.17 ppm and that for Pt–⁷⁹Br and Pt–⁸¹Br is 0.03 ppm.²³ Therefore in principle it is possible to count the number of Cl and Br ligands bonded directly to Pt via the isotope-splitting pattern. But in practice it is difficult to resolve such multiple patterns because of line broadening, which is due to either relaxation mechanism or temperature drift. The latter is a problem since the chemical shift of ^{195}Pt is strongly temperature-dependent (up to 1 ppm/K).

^{14}N NMR spectroscopy can be useful for ammine (–NH₃) and amine (–NH₂, –NH) groups which coordinate to Pt. Since ^{14}N is a quadrupolar nucleus (Table 2), and quadrupolar relaxation is dominant when the environment of ^{14}N has a low symmetry. This leads to broad resonances and subsequently reduces the sensitivity. However, the quadrupolar nature of ^{14}N has the beneficial effect of shortening the relaxation rate and allowing rapid pulsing so that a large number of transients can be acquired. It is still possible to follow reactions of cisplatin in blood plasma and cell-culture media at millimolar drug concentrations and to monitor ammine release.²⁴

^{15}N NMR is particularly useful in the study of the aqueous chemistry of cisplatin and other platinum ammine/amine compounds since ^{15}N -labeled compounds can readily be prepared. More importantly, both the ^{15}N NMR chemical shift (Figure 2) and the $^1J(^{15}\text{N}–^{195}\text{Pt})$ coupling constant are sensitive to the nature of the *trans*-ligand in Pt–NH₃ (or Pt–NH₂) complexes which provide useful information for identifying the ligands in the coordination spheres of Pt²⁺ (and Pt⁴⁺) (Figure 2). This technique has been used to characterize the reaction products of ^{15}N -labeled cisplatin.²⁵

The low receptivity of ^{15}N (3.85×10^{-6} relative to ^1H) limits its usefulness for directly detected ^{15}N -NMR studies of cisplatin and related platinum ammine/amine complexes in biofluids. The sensitivity of detection can be improved to some extent by ^{15}N isotopic enrichment and further enhanced

**Figure 2** Variation of ^1H and ^{15}N chemical shifts with the *trans*-ligand in Pt^{II}–NH, Pt^{II}–NH₂ and Pt^{II}–NH₃ complexes. (Adapted with permission from Ref.^{9b})

by polarization transfer from ^1H via for example, DEPT and INEPT experiments. But in practice, this enhancement of ^{15}N signal will be affected by the rate (k_{ex}) of exchange of protons between an ammine (and amine) and a solvent (e.g., water), and is hampered by rapid chemical exchange ($k_{\text{ex}} > J$). The maximum enhancement in ^{15}N signal via polarization transfer is only 9.8 (i.e., $\gamma_{1\text{H}}/\gamma_{15\text{N}}$). The repetition time of the pulse sequence is governed by the ^1H rather than the longer ^{15}N spin-lattice relaxation (T_1) which allows more rapid pulsing. $^{15}\text{N}\{^1\text{H}\}$ DEPT NMR techniques have been allowed the detection of rapidly changing intermediates in the reaction of ^{15}N labeled cisplatin with glutathione and also of ammine release following interaction of cisplatin with intracellular components of intact red blood cells at concentrations as low as 1 mM.²⁶ This method can be of values in situation where ^1H NMR resonances are very broad.

However, inverse ^{15}N methods ($^1\text{H}\{^{15}\text{N}\}$) are often preferred due to the greatly improved sensitivity for detection, by a theoretical maximum of 306 ($(|\gamma_{1\text{H}}|/|\gamma_{15\text{N}}|)^{5/2}$) with respect to directly detected ^{15}N . This technique is based on the large one-bond $^1J(^{15}\text{N}–^1\text{H})$ coupling constant (ca. 70 Hz for $^{15}\text{NH}_3$) and it is necessary to work in H₂O (90% H₂O) since the NH protons normally exchange with deuterium rapidly in D₂O. The exchange of NH with solvent is much faster for Pt⁴⁺ than for Pt²⁺ complexes at neutral pH. Besides the high sensitivity, inverse detection also brings a simplification of complicated spectra since it selectively detects those protons directly attached to the labeled ^{15}N in the sample (e.g., Pt–NH₃), by use of the heteronuclear single (or multiple) quantum coherence transfer (HSQC or HMQC) pulse sequence. Each distinct type of Pt–NH resonance appears as a singlet, sometimes together with broadened ^{195}Pt satellites if ^{15}N decoupling is employed during the acquisition period (e.g., GARP method²⁷). Water suppression can be achieved by the use of pulse sequences incorporating pulsed field gradient (which can be employed for both coherence selection and suppression of water signal).²⁸

Figure 3 [^1H , ^{15}N] spectrum (left) of a 5 mM solution containing ^{15}N -cisplatin and its hydrolysis products in 95 : 5 = $\text{H}_2\text{O}/\text{D}_2\text{O}$ at pH 4.72, 300 K. ^{15}Pt satellites are marked on the 1D ^1H spectrum with an asterisk. Plots of the ^1H shifts of Pt-NH_3 vs. pH allow direct determination of the $\text{p}K_a$ values (right). (Adapted with permission from Ref.²⁹)

A one-dimensional ^1H spectrum (the first increment in a 2D experiment) contains only protons which are directly attached to the labeled ^{15}N in the sample ($\text{Pt-}^{15}\text{NH}$) and all others are eliminated. The combined detection of ^1H and ^{15}N in a reverse experiment, '2D [^1H , ^{15}N] HSQC NMR', is extremely powerful since the ^{15}N chemical shift range is large and diagnostic of the *trans*-ligand (Figure 2). The ^{15}Pt satellites in a 2D [^1H , ^{15}N] spectrum sometimes appears as diagonal peaks which correspond to the $^2J(^1\text{H-}^{15}\text{Pt})$ and $^1J(^{15}\text{N-}^{15}\text{Pt})$ coupling constants (again diagnostic) in the ^1H and ^{15}N dimensions, respectively (Figure 3) if they are not broadened beyond detection. The 2D [^1H , ^{15}N] method with ^{15}N -labeled platinum anticancer agents is particularly useful in studies of body fluids or cell culture media since thousands of overlapping ^1H resonances from other substances are filtered out. It takes just a few minutes to acquire a 2D [^1H , ^{15}N] spectrum at millimolar concentration and it is possible to detect ^{15}N -labeled species at concentrations as low as 20 μM .

2.2 Activation of Platinum Anticancer Drugs and Their Interaction with Nucleotides and DNA

It is widely accepted that the ultimate target for platinum anticancer drug is DNA and Pt-OH_2 bonds are much more reactive toward DNA and other biomolecules than Pt-Cl or Pt-OH bonds. The mechanism of action of cisplatin is believed to involve activation via hydrolysis inside cells where the concentration of chloride (Cl^-) (ca. 4 mM) is much lower than outside cells (ca. 104 mM). Therefore it is important to determine the rates of hydrolysis and $\text{p}K_a$ values of the

hydrolysis products. By the use of 2D [^1H , ^{15}N] HMQC spectroscopy, the $\text{p}K_a$ values can be rapidly measured at low concentration (Figure 3). By fitting the shift changes of ^1H NMR and ^{15}N -NMR as a function of pH, the $\text{p}K_a$ values of the monoaqua *cis*- $[\text{Pt}(\text{NH}_3)_2\text{Cl}(\text{H}_2\text{O})]^+$ (6.41) and diaqua adducts *cis*- $[\text{Pt}(\text{NH}_3)_2(\text{H}_2\text{O})_2]^{2+}$ (5.37 and 7.21) were determined.²⁹ The equilibrium constant for the first stage of cisplatin hydrolysis was also determined to be 2.72 based on the resonance integration of reacted cisplatin, and the mono- and di-aqua adducts. Since all hydrolysis products can be readily distinguished in the spectrum, the problems associated with other methods are overcome. The $\text{p}K_a$ values of aqua ligands of related platinum anticancer complexes such as *cis*- and *trans*- $[\text{Pt}(\text{NH}_3)(\text{cyclohexamine})\text{Cl}_2]$, and *cis*- $[\text{Pt}(\text{NH}_3)(2\text{-Pic})\text{Cl}_2]$ (2-Pic is 2-methyl-pyridine), have also been determined by this [^1H , ^{15}N] NMR method.^{30,31} The rate of hydrolysis for each chloride (Cl^-) ligand of *cis*- $[\text{Pt}(\text{NH}_3)(2\text{-Pic})\text{Cl}_2]$ was determined by the time-dependence of the [^1H , ^{15}N] NMR spectra for a period of over 20 h and was found to be slower than cisplatin.³¹

The reactions between ^{15}N -labeled cisplatin and guanosine-5'-monophosphate (5'-GMP) have also been investigated in aqueous solution by NMR spectroscopy.³² The short-lived reactive species *cis*- $[\text{Pt}(\text{NH}_3)_2\text{Cl}(\text{H}_2\text{O})]^+$ was detected during the early stages, followed by the formation of the mono- and bis-GMP adducts (Scheme 2). Hydrogen-bonding interactions were suggested to occur between N-H protons in Pt-NH_3 and deprotonated 5'-phosphate of GMP. Similar behavior was also observed between the N-H protons in ^{15}N -labeled ethylenediamine platinum complex $\{\text{Pt}(\text{en})\}^{2+}$ with GMP and adenosine monophosphate (AMP).³³

Figure 4 2D [^1H , ^{15}N] HSQC-NMR spectrum of 14-mer duplex d(ATACATG*G*TACATA)-d(TATGTACCATGTAT) after reaction with ^{15}N -cisplatin for 8 h. Labels: *, ^{15}Pt satellites; ‡, artefact. Peaks are assigned: 1, cisplatin; 2, $\text{cis-}[\text{Pt}(\text{NH}_3)_2\text{Cl}(\text{H}_2\text{O})]^+$; 3, $\text{cis-}[\text{Pt}(\text{NH}_3)_2\text{Cl}(\text{N}(7)\text{-G}(7))]^+$; 4, $\text{cis-}[\text{Pt}(\text{NH}_3)_2\text{Cl}(\text{N}(7)\text{-G}(8))]^+$; 5/6, $\text{cis-}[\text{Pt}(\text{NH}_3)_2\text{Cl}(\text{N}(7)\text{-G}(18/25))]^+$; 7,8, $\text{cis-}[\text{Pt}(\text{NH}_3)_2(\text{N}(7)\text{-G}(7))(\text{N}(7)\text{-G}(8))]^+$ (distorted and kinked forms). (Adapted with permission from Ref.³⁵)

The detailed kinetics for the interaction of cisplatin with 10- and 14-mer oligonucleotides have been investigated. The major species in the pathways of platination of mono- and bi-functional adducts (both single- and double-strand GG adducts) can be simultaneously detected in a single [^1H , ^{15}N] NMR experiment (Figure 4).^{34,35} The aqua-chloro intermediate which was usually present at micromolar concentrations, is readily monitored in these experiments and its lifetime was determined (ca. 8 min at 310 K) directly for the first time. Kinetic data obtained by [^1H , ^{15}N] NMR techniques are in close agreement with those determined by ^{195}Pt NMR spectroscopy (with enriched ^{195}Pt).¹⁴ However, no aqua-chloro intermediate was detected previously by ^{195}Pt NMR during the course of the reaction with DNA. As expected, the reactions of cisplatin proceed via an aqua-chloro intermediate, and lead to two monofunctional adducts on the duplex and two on the GG-containing single strand. One of the GG residues is platinated three-fold faster than the other, which is in line with the results obtained by HPLC,³⁶ and ring closure to form a GG chelate on the duplex (3'-G) occurs also faster by about an order of magnitude for one monofunctional adduct than the other. Surprisingly, the 5'-G monofunctional adduct on the duplex has a very long lifetime (over 5 days at 298 K).^{35,37} CD, ^1H and [^1H , ^{15}N] NMR

data have shown that the 14-base GG-platinated DNA duplex d(ATACATG*G*TACATA)-d(TATGTACCATGTAT) where G*G* is platinated guanine (at N7) by the $\text{cis-}[\text{Pt}(\text{NH}_3)_2]^{2+}$, undergoes a reversible pH-induced structural transition ($\text{p}K_a$ 4.8) between kinked-duplex and distorted forms. Binding of platinated duplex to the high-mobility-group protein 1 (HMG1) box A is at the concave face of the protein, and the kinked duplex may be converted to a different distorted form.³⁸ It is known that platinum forms bifunctional DNA adducts with the following order of sequence preference: $-\text{GG}- > -\text{AG}- \gg -\text{GA}-$ and that DNA platination is kinetically controlled. There is a clear preference for the formation of monofunctional adduct of cisplatin with $-\text{AG}-$ over the $-\text{GA}-$ sequence as judged from [^1H , ^{15}N] a HSQC NMR study. Closure to form the bifunctional adduct is more rapid in the former case than in the latter.³⁹ This could explain, at least in part, why $-\text{AG}-$ bifunctional adducts are preferentially formed and few platinated $-\text{GA}-$ adducts are observed.

2.3 Structures of Platinated Oligonucleotides

The anticancer activity of cisplatin and related complexes is believed to result from strong bonding of platinum to DNA affording mainly intrastrand $-\text{GG}-$ and $-\text{AG}-$ cross-links, the local structure of which are subsequently modified in such a way that apoptosis is induced.⁴⁰ The presence of these DNA cross-links in cisplatin-treated cancer patients correlates with positive responses to treatment with the drug.⁴¹ Such lesions have deleterious effects on DNA replication and transcription and cause mutations.^{42,43} Previous studies have shown that platinated-DNA was recognized by proteins containing one or more high-mobility-group (HMG) domains^{44–46} and structure-specific recognition protein 1.⁴⁷ The shielding of excision-repair caused by the binding of HMG proteins to DNA has been confirmed by both in vitro and in vivo experiments.^{48,49} Elucidation of the structural distortion of the cisplatin (and related complexes) DNA adduct at the molecular level is definitely an important step toward understanding the activity of platinum anticancer drugs.

Various techniques especially those of X-ray crystallography and NMR spectroscopy, can be utilized to study the structure of platinated DNA adducts, but NMR spectroscopy is the focus of this paper. ^1H NMR is particularly useful for studying DNA and almost all of the modern NMR techniques can be used. Additional information can be obtained from studies with other nuclei such as ^{13}C , ^{15}N , ^{31}P and ^{195}Pt . Platinated DNA structures were determined based on observed 1D and 2D NMR data (e.g., NOE) with the aid of molecular mechanics and dynamics calculations, and have been reviewed previously.⁵⁰

The structures of a number of platinated DNA adducts at either d(G*pG*) or d(A*pG*) sites have been solved and are listed in Table 3.^{51–60} Platinum cross-link induced structural distortion seems to be a common feature. The solution structure of the platinated octameric duplex d(CCTG*G*TCC)-d(GGACCAGG) shows that it is unwound by $\sim 21^\circ$, and kinked by $\sim 58^\circ$ toward the major groove at the d(G*pG*) site (Figure 5A). The minor groove is significantly widened and flattened at the platination site.⁵¹ The overall features are similar to those observed for the crystal structure of the platinated dodecameric duplex.⁶¹ The platinated duplex d(GCCG*G*ATCGC)-d(GCGATCCGGC) is also kinked by

Table 4 Lists of NMR structures of platinated DNA

~60° toward the major groove at the Pt²⁺ coordination site and unwound by 12–19°. ⁵² The solution structure of the platinated dodecamer duplex was reported recently. The *cis*-[Pt(NH₃)₂]²⁺-d(G*pG*) lesion causes the two adjacent –G*G*–bases to roll toward one another by 49°, leading to an overall helix kink by 78°. ⁵³ The helix deformation in solution is greater than that in crystal, and the structural differences may be attributable to crystal packing interactions. The structure of a AT-rich DNA 14-mer d(ATACATG*G*TACATA)·d(TATGTACCATGTAT) was determined and it was suggested that the bend of DNA induced by cisplatin is sequence dependent. ⁵⁴ Platination causes the overall DNA duplex to bend by ~52° toward the 3-end [with respect to the d(G*pG*) strand], in contrast to those GC-rich structures which bend toward the 5-end. The minor groove opposite the platination site is again widened and flattened. The solution structure of the d(G*pG*) platinated adduct of the nitroxide spin-labeled complex *cis*-[Pt(NH₃)(4-amino-TEMPO)]²⁺ (TEMPO = 2, 2, 6, 6-tetramethylpiperidinyloxy) with the undecamer duplex has been determined by using conventional NMR methods (e.g., NOE studies) and long-range (10–20 Å) proton–electron distance constraints. ⁵⁶ The use of long-range distance constraints did not affect the local geometry of the adduct only the global structure, but allows a better definition of the global structures of the duplexes. The platinated DNA duplex d(CTCA*G*CCTC)·d(GAGGCTGAG) cross-linked at the d(A*pG*) sequence by *cis*-[Pt(NH₃)₂]²⁺ also bends to the double helix towards the major groove in a way similar to that observed for the d(G*pG*) crosslink. ^{52,57} Molecular modeling based on published NMR and X-ray data suggested that all duplexes in the three-base-pair d(XpG*pG*) and d(XpA*pG*) region are very similar and protein binding does not greatly change the structure of this region. ⁶²

Interstrand d(G*pG*) crosslinks formed by cisplatin with oligomers have also been studied. ^{58,59} They occur predominantly between two guanines on opposite strands, which requires a distance of ca. 2.8 Å between the two N7 atoms. As for the intrastrand crosslink, the interstrand crosslink also causes a kink in the DNA helix. However, unlike the intrastrand crosslink, the kink and unwound is toward the minor groove. The deoxyribose of the platinated deoxyguanosine (G) is inverted so that O4' is pointing in the opposite direction to that of the remaining nucleotides. In addition, the complementary deoxycytidines (C), which were originally

Figure 5 NMR refined structures cisplatin-induced intrastrand (A) and interstrand cross-linked DNA duplex (B). The DNA is significantly altered from the B-form to accommodate cisplatin in (A), and the deoxycytosine residues originally base-paired to the platinated guanine have become extrahelical (B). Color code: C, green; H, metallic white; N, blue; O, red; P, orange; Pt, yellow. (Adapted with permission from Refs. ^{51,58})

base-paired to the platinated G are extruded and become extrahelical (Figure 5B). ⁵⁸ The localized change from B-DNA to a left-handed Z-DNA structure around the platination site was also observed. *Cis*-[Pt(NH₃)₂]²⁺ is also located in the minor groove of d(CCTCG*CTCTC)·d(GGAGCG*AGAG). The stacking of the two cross-linked guanines with the neighboring bases induces a kink of 40° toward the minor groove.

The 1,3-intrastrand d(G*XG*) (where X is C or T) cross-link minor adduct does not distort the global helical structure to the extent observed in the 1,2-intrastrand cross-link discussed above, but significantly disrupts local base-pairing and stacking at the 5'-end. The helix is bent by 24° and unwound by 19°. The platinum lesion causes a severe roll of 5'-G6 towards the major groove. ⁶⁰

2.4 Interaction with Amino Acids, Peptides and Proteins, and Their Metabolites in Biofluids

Increasing evidence has shown that platinum–peptide (amino acid and protein) interactions and particularly platinum–thioether interactions, play an important role in the mechanism of action of platinum drugs. The use of NMR

spectroscopy for studying these interactions has been summarized previously,⁹ and Pt–methionine complexes with various isomers have been characterized by ^{13}C , ^{15}N , and ^{195}Pt NMR. In fact, it has been shown that platinum species can initially bind to thioether groups and then migrate to N7 of guanine.^{63,64} ^1H and $[\text{}^1\text{H}, \text{}^{15}\text{N}]$ NMR spectroscopy has shown that L-methionine (Met) increases the rate of reaction of cisplatin with guanosine 5'-monophosphate (5'-GMP) at pH 7.⁶⁵ Therefore, methionines in peptides and proteins could play a role in the transfer of platinum onto DNA. Activation of carboplatin by reaction with L-Met derivatives could also provide an important pathway since carboplatin hydrolyses and interacts with chloride too slowly to account for its biological activity. Reaction with L-Met leads to a surprisingly stable ring-open intermediate with a half-life time 28 h at 310 K. By use of the 2D $[\text{}^1\text{H}, \text{}^{15}\text{N}]$ HSQC NMR method, a species with ^1H and ^{15}N shifts very similar to this intermediate was detected as a major metabolite in the urine samples from mice treated with ^{15}N -carboplatin.⁶⁶ This suggests that the ring-open intermediate is probably present in urine after carboplatin administration.

The thiolate-containing peptide glutathione (γ -L-Glu-L-Cys-Gly, GSH) is present in cells at mM concentrations. Various transient intermediates formed between the platinum complex and GSH during the reaction as judged by multinuclear NMR,^{9b,67} and a novel dinuclear platinum GSH complex was also isolated and its structure was proposed based on ESI-MS and various advanced 2D NMR techniques.⁶⁸ In contrast to thioethers, the binding of Pt^{2+} to thiolate tends to be irreversible and ammine/amine ligands will finally be released from initial complex. Reactions between cisplatin and intracellular thiols such as GSH may therefore inactivate the drug and moreover the Pt–GSH complex can be pumped out of the cisplatin-resistant cells.

There are conflicting reports on the role of Pt–protein adducts in the mechanism of action. On the one hand, it has been postulated that the binding of cisplatin to protein is probably the cause of many of the drug's side-effects, while on the other hand several reports suggest that Pt^{2+} -albumin adducts may be anticancer active. One day after intravenous infusion of cisplatin, 65–98% of the platinum in blood plasma is protein bound.^{69,70} Human serum albumin (66 kDa) is thought to be the major binding sites for cisplatin in human blood plasma. In contrast to previous reports, 1D and 2D $[\text{}^1\text{H}, \text{}^{15}\text{N}]$ NMR data suggest that ^{15}N -cisplatin mainly reacts with the methionine residues of albumin forming Met-S,N-macrochelates together with minor monodentates Met-S adduct and Cys34, the only free thiol of the protein.⁷¹ The iron binding protein transferrin (ca. 80 kDa) could deliver platinum to tumor cells, which are known to overexpress transferrin receptors. Diferric transferrin is taken up by cells via the known process of 'receptor-mediated endocytosis'. A combination of 2D $[\text{}^1\text{H}, \text{}^{13}\text{C}]$ and $[\text{}^1\text{H}, \text{}^{15}\text{N}]$ NMR spectroscopic studies using labeled transferrin (ϵ - $[\text{}^{13}\text{C}]$ Met labeled protein) and ^{15}N -cisplatin has shown that preferred Pt^{2+} binding site appears to be Met256 with an additional site at the surface-exposed methionine.⁷²

2.5 Other Metallo-anticancer Agents

Besides platinum, other metal complexes also have promising anticancer activity.^{2,3} Gallium nitrate is known to exhibit anticancer activity and is now being used clinically for the treatment of cancer-induced hypercalcemia. The octahedral Ru^{3+} complexes (low spin d^5) are more active against metastases than primary tumors, and may be prodrugs which are bio-reduced to Ru^{2+} species inside cells. Paramagnetically shifted ^1H NMR resonances are readily detected in ^1H spectra of Ru^{3+}

Figure 6 ^{71}Ga NMR spectra of ovotransferrin (1.3 mM, pH 7.6). (A) Before (bottom) and after addition of one (middle) and two mol equiv (top) of Ga^{3+} in the presence of 20 mM NaHCO_3 . (B) ^{71}Ga NMR spectra of Ga_2 -ovotransferrin (bottom), C-lobe of ovotransferrin (oTF/2C, 0.35 mM, 1.0 mol equiv of Ga^{3+}), and N-lobe of ovotransferrin (oTF/2N, 0.35 mM, 1.0 mol equiv. Of Ga^{3+}) in the presence of $\text{Na}_2\text{C}_2\text{O}_4$. (Adapted with permission from Ref.⁷⁵)

complexes and were used to determine the rate of hydrolysis of the anticancer agent *trans*-[RuCl₄(Im)₂][−] where Im is imidazole.⁷³ Interestingly, both Ru³⁺ and Ga³⁺ are thought to be delivered by human transferrin (hTF).^{2–4,74} It is known that many solid tumors express more transferrin receptor than normal cells. The binding properties of Ga³⁺ to ovotransferrin were investigated by ¹³C and ⁷¹Ga NMR. The latter technique is extremely useful at very high field once gallium has bound to large biomolecules.⁵ Ga³⁺ interacts preferentially with the N-lobe of the protein when carbonate is present as the synergistic anion, but enters equally both the N- and C-lobes of the protein when oxalate is the anion (Figure 6).⁷⁵ The binding of Ru³⁺ complexes to lactoferrin is at the imidazole of His253, one of the iron ligands in the iron binding cleft of the N-lobe, and is reversible with Ru release at pH 4–5 or in the presence of a large excess of citrate or adenosine triphosphate (ATP).

The organometallic titanocene and another Ti⁴⁺ complex have entered phase II and I clinical trials for anticancer, respectively. We have demonstrated by UV and various NMR spectroscopies that the Ti⁴⁺ complex binds strongly to human serum transferrin at the specific iron (Fe³⁺) site.⁷⁶ 2D [¹H, ¹³C] studies of ε-[¹³C]Met-hTF have shown that Ti⁴⁺ loads the C-lobe first followed by the N-lobe. Titanium (Ti⁴⁺) bound transferrin effectively blocked cell uptakes of ⁵⁹Fe-hTF into BeWo cells,⁷⁷ which indicated that titanium transferrin could be recognized by transferrin receptor and be taken up into cells.

3 GOLD ANTI-ARTHRITIC DRUGS

Several injectable Au⁺ thiolate drugs such as aurothiomalate and the oral drug auranofin are widely used for the treatment of difficult cases of rheumatoid arthritis and reviews on the medical use of gold have been published.^{78–80} The injectable Au⁺ complexes are polymers with thiolate sulfurs bridging to linear Au⁺, in chain or cyclic structures. The crystal structure of aurothiomalate has shown that linear S–Au–S units are arranged into polymeric double-helical structures.⁸¹ The structures of these polymers were found to be very sensitive to the ionic strength and pH of the solutions. Most of gold thiolate drugs often contain a small mol excess (10–15%) of thiol over gold.

One feature of these linear Au⁺ drugs is that they undergo facile thiolate exchange reactions and ¹³C NMR studies have shown that thiols with lowest pK_a values bind most strongly to Au⁺.⁸² The administered drugs are probably not the active species. Gold(I) is a soft metal and therefore has a very high affinity for soft ligands such as thiolate sulfurs, but binds only weakly to nitrogen and hardly at all to oxygen. Consequently proteins (and enzymes) containing thiolate groups (Cys residues) particularly those with low pK_a

values are targets for Au⁺. In blood, a major site for gold transport is Cys34 of serum albumin which has a low pK_a (~5). For the oral gold drug, ³¹P NMR has been extensively used to probe speciations in proteins, bio-fluids and cells.^{83–86} The ³¹P chemical shift of bound phosphine (Au–PEt₃, where Et is ethyl) is sensitive to the nature of the coordinated ligands (X) and release of PEt₃ can readily be detected. The PEt₃ (and thiomalate) ligands of auranofin (and aurothiomalate, AuStm) are initially retained on binding of gold to albumin:

Moreover, the ³¹P chemical shift of bound phosphine in RS–Au–PR₃ was found to correlate with the pK_a of thiolates (SR).^{82,86} ¹H and ³¹P NMR studies have shown that the rate of binding of gold drugs to albumin appears to be determined by the rate of opening of the cleft in which Cys34 is situated.^{87,88} Surprisingly, binding of auranofin and related gold compounds to Cys34 of albumin induces a structural transition, the effect of which can readily be observed by imidazole εCH¹H NMR resonances of His3 of the protein (Figure 7).^{88,89} Such communication between His3 and Cys34 may be explained by small changes in the arrangement of intervening helices 1 and 2 of domain I of the protein. This may be mediated by a *cis-trans* isomerization of Pro35, changing the environment of Cys34 from a buried to an exposed form. The structural change can also be induced by blocking Cys34 as a disulfide, e.g., cystine. Such a structural transition of albumin induced by gold drugs has even been detected in intact blood plasma by ¹H NMR spectroscopy.⁹⁰ The exposed position of bound gold may have important implications for the transport and bioavailability of gold–drug metabolites.

Cyanide appears to play an important role in the metabolism of gold drugs. It can readily replace the thiomalate ligand from aurothiomalate in vitro and Au(CN)₂[−] has been shown to be a metabolite of gold drugs in vivo.^{91,92} The enhanced uptake of gold into red blood cells of smokers is due to the formation of this species after inhalation of HCN in cigarette smoke. Interaction of aurothiomalate and cyanide (¹³C-enriched CN[−]) was followed by ¹H and ¹³C NMR spectroscopy.⁹² The mixed-ligand complex [(Stm)Au(CN)][−] (Stm=S-bound thiomalate) readily forms as an intermediate when [CN[−]]/[aurothiomalate] < 2, and Au(CN)₂[−] is the major species at higher ratio. Mixed-ligand complex of aurocyanide with other thiolate molecules such as glutathione, cysteine and captopril have also been reported.^{92–95} Thiols and cyanide both bind to Au⁺, although as expected, cyanide (CN[−]) binds more strongly. Under biological conditions where [thiols] ≫ [HCN], substantial displacement of cyanide may take place. This may facilitate the accumulation of gold by red cells where the intracellular glutathione concentration is high (mM). An aurocyanide complex of albumin was recently studied by ¹³C NMR spectroscopy and other techniques. There are two distinct binding mechanisms: the dominant mechanism is reversible association (non-specific binding) of intact Au(CN)₂[−] (δ_{13C} = 156.4) to albumin to form Alb-[Au(CN)₂]_n (δ_{13C} = 154.7, broad signal).⁹⁶ The second binding mechanism is at Cys34 to form Alb-Cys34Au(CN) via a ligand exchange reaction which accounts for only a minor fraction of the bound-gold (ca. 11%).

4 LITHIUM FOR MANIC DEPRESSION

Lithium is an element discovered over 177 years ago (1817), but it was not until the seminal work of the Australian scientist, John Cade 50 years ago,⁹⁷ and subsequent clinical studies by Mogens Schou, that lithium was seen by modern psychiatry as an effective treatment for manic depression. Both lithium carbonate and citrate compounds are widely used as a prophylactic treatment for bipolar disorders.⁹⁸ Doses are normally gram quantities and the therapeutic level of lithium in serum is about 0.4–1.2 mM, and clinical efficacy usually takes 1–2 weeks to become established. Previous studies have shown that lithium was widely distributed in the body following oral administration due to its high lability and its weakness towards complexation.

Despite intensive research, the biochemical basis for lithium's therapeutic effects still remains to be fully elucidated. Lithium ions are small but highly hydrated and could interfere with Mg²⁺ biochemistry due to their comparably high charge densities, the so-called 'diagonal relationship' between Li⁺ and Mg²⁺. However, the favored mode of action of lithium

is probably by interference with Ca²⁺ metabolism via inhibition of the inositol phosphate pathway.^{99–101} Lithium also stimulates glutamate release and protects neurons by inhibiting N-methyl-D-aspartate receptor-mediated calcium influx.^{102,103} Determination of lithium is normally made by spectroscopic methods, e.g., atomic absorption and nuclear magnetic resonance. The former involves the disruption of samples (e.g., cells) and ensuing tedious separation. In addition, the atomic absorption measurements are not specific to the intracellular compartments. By contrast, NMR provides a non-invasive and direct way to investigate lithium in cells and tissues.¹⁰⁴

Naturally occurring lithium consists of two isotopes ⁶Li and ⁷Li, with natural abundance 7.42 and 92.58%, respectively (Table 2). Both isotopes are weakly quadrupolar and the quadrupole moment of ⁶Li is the smallest known while that of ⁷Li is amongst the smallest, and they both give narrow resonance lines and have long spin-lattice relaxation times (*T*₁).¹⁰⁵ However, ⁷Li is the choice for most biological studies because of its high sensitivity, higher natural abundance and more favorable relaxation as compared with ⁶Li. The chemical shift range of ⁷Li is small (ca. 15 ppm) due to its simple electronic structure and aqueous chemistry. The NMR spectrum of ⁷Li generally contains a single peak corresponding to the overlapping signals from different environments, e.g., intra- and extra-cellular. It is possible to differentiate ⁷Li signals from different compartments, for example, ions within the cells and those that are free in the extracellular bathing fluid, based either on their different relaxation properties or with the aid of shift reagent (e.g., dysprosium tripolyphosphate), Figure 8.¹⁰⁶ Shift reagents, which are negatively charged lanthanide complexes and are insoluble in hydrophobic cell membrane, are repelled by the negatively charged head groups of phospholipids at the surface of cell membranes. In contrast to other alkali metals, ⁷Li (*I* = 2/3) actually resembles a spin 1/2 nucleus and relaxation tends to be dominated by the dipolar mechanism.

The application of ⁷Li and NMR of other alkali-metals to study the interaction of these metal ions with metalloproteins have been reviewed.¹⁰⁷ The chemical shifts of ⁶Li, ⁷Li and other alkali metal ions except Cs⁺, are normally insensitive to either solvation or complexation by biomolecules. Li binds to myo-inositol monophosphatase, an enzyme that is inhibited by lithium and is thought to be the primary target for lithium therapy, and induces a downfield shift by <0.1 ppm and broadening of the ⁷Li NMR signal. The binding constant at a single site was calculated to have a *K*_d of 1 mM, and lithium was found to compete with group II metal ions such as Mg²⁺ at that site.¹⁰⁸ NMR investigation of Li⁺ binding to phospholipids and cell membrane have also been reported.

In order to get into the brain where the site of action of lithium is, Li⁺ must be absorbed through the gastrointestinal tract into blood and pass the blood brain barrier. Clearly the membrane transport of lithium is a critical feature and several different NMR techniques have been used depending on the time-scale of the lithium transport process. The best model available for the study of Li⁺ transport in human cells is the erythrocyte, which is also believed to be a good model for the blood brain barrier. Numerous NMR studies of Li⁺ transport and environment in erythrocytes have been reported.^{109,110} Depressed patients with a high [Li]_i/[Li]_e ratio, where 'i' and 'e' represent intra- and extra-cellular concentration of lithium, were found to have a better therapeutic response that

Figure 8 ^7Li NMR spectra of rat blood samples with added shift reagents (dysprosium tripolyphosphate, $\text{Dy}(\text{ppp})_2^{7-}$). The peaks at 0 and ca. -10 ppm correspond to intracellular and extracellular ^7Li , respectively. The various doses of LiCl administered to the rats are indicated next to each spectrum. (Adapted with permission from Ref.^{110b})

those patients with a lower ratio.¹⁰⁹ It was suggested that erythrocyte Li concentration could serve as a useful indicator of clinical response. However, subsequent studies were unable to substantiate the initial findings, and it is now generally accepted that this parameter is not clinically useful partly due to large interindividual variations in ionic transport process. It is known that a considerable amount of Li^+ enters the erythrocytes with the $[\text{Li}]_i/[\text{Li}]_e$ ratio typically at 0.3–0.6 which indicated that Li is actively extruded from the cells. Higher ratios have been reported recently in the low dose range in rats (Figure 8) and the coadministered drug, thioridazine, has no effect on erythrocytes and plasma lithium levels.^{110b,c}

In spite of extensive investigations of erythrocytes, little is known about the transport behavior of Li^+ in other cells and major differences are expected between erythrocytes and the excitable, nucleated cells of the central nervous system such as neurons and glia. Li^+ transport processes and intracellular concentrations in the brain have been approached by using human nerve 1321 N1 astrocytoma. ^7Li NMR spectroscopy showed that the uptake of Li^+ was approximately ten times faster than that into human erythrocytes and the steady-state was reached within 60 min. The low intracellular Li^+ concentration ($[\text{Li}]_i/[\text{Li}]_e \sim 0.3$) suggested the presence of an efflux mechanism in astrocytomas. Similar results have been obtained very recently for cultured human neuroblastoma SH-SY5Y cells.^{112,113} Intra- and extra-cellular ^7Li resonances could be resolved in the presence of the shift reagent and relaxation measurements showed that Li^+ is immobilized more in human SH-SY5Y cells than in human erythrocytes.

Significant increases in the first-order rate constants for Li^+ influx and efflux in the presence of veratridine (0.05 mM) suggested the Li^+ transport was mediated via Na^+ channels, a pathway not present in erythrocytes.¹¹³ The studies of cultured central-nerve-system cells will also provide important information for in vivo study.

Direct investigation of Li^+ in the brain may be a better measure of efficacy or neurotoxicity than that in the serum. The spatial distribution of Li in the brain may also shed light on the still unknown mechanism of action of Li. Due to its relatively high sensitivity, the sufficiently high enough concentration of Li in tissues and most importantly the development of NMR spectroscopy in vivo, ^7Li NMR has successfully been used in recent years as a new tool to measure brain tissue lithium concentration.^{104,114–117} Renshaw and coworkers' pioneering work demonstrated the feasibility of in vivo tissue measurements of lithium in animal and in human subjects.^{118,119} In animals, efforts have been made to develop methods for measuring the pharmacokinetics of uptake in brain. It was found that the time constant for the uptake of a single dose of Li in rat brain was 48–98 min with signals that were uncontaminated by those from surrounding tissues.¹²⁰ Because of the high dose and long acquisition times used, the distribution of Li in the rat brain could be determined by ^7Li NMR imaging although the resolution of these imaging is overall quite poor.^{121,122}

Most recent ^7Li work in vivo has focused on humans. Initial unlocalized studies measured the kinetics of uptake and elimination of ^7Li and compared serum and brain concentrations. Several studies have confirmed that the concentration of Li in brain is typically 0.1–0.6 mM and indicated brain/serum ratios of 0.4–0.7. Preliminary studies have attempted to examine a possible relationship between brain Li levels and therapeutic response, suggesting that Li brain levels may be of clinical relevance.^{123–125} However, this question has yet to be properly addressed in patient samples large enough to provide a more clear answer. The potential for ^7Li in vivo NMR as an important tool for investigation of Li^+ refractoriness and predication of treatment outcome in bipolar disorder patients is currently being investigated.^{116,126}

5 BISMUTH ANTIULCER (AND ANTIMONY ANTILEISHMANIA) AGENTS

Arsenic, antimony and bismuth have long been associated with medicine. Currently antimony compounds are used clinically for the treatment of leishmaniasis and bismuth compounds are widely used as antiulcer drugs (Table 1). Recently clinical studies in China demonstrated that the classical inorganic compound, arsenic trioxide (As_2O_3) can induce remission in patients with acute promyelocytic leukemia (APL, a rare blood cancer).^{127,128} The induction of apoptosis and partial differentiation may be responsible for the activity of this metal.¹²⁹ Progress in the understanding the mode of action and design of drugs based on these elements are being greatly held up through lack of a suitable probe for the metal itself. NMR studies of these complexes have therefore relied on the observation of ligand nuclei such as ^1H and ^{13}C . The binding of citrate to Bi^{3+} in antiulcer complexes has been studied by ^1H , ^{13}C and $[\text{H}, ^{13}\text{C}]$ NMR spectroscopy.^{130–132} Citrate is a good bridging ligand and polymeric species are

formed in solution. The structures of bismuth citrate complexes are complicated, being dependent on pH, concentration, [Bi : citrate] ratio and the counter cations present. Different bismuth citrate species are in fast exchange on the NMR time-scale at pH < 6.2; the exchange rate decreases at pH > 6.2, and different species can be observed.^{130,131} By means of diffusion-ordered 2D [¹H, ¹³C] HSQC NMR spectroscopy together with isotope-labelling of citrate (¹³C2/¹³C4), a wide range of different types of bound citrate can readily be detected at low Bi concentrations (5 mM) in aqueous solutions of ranitidine bismuth citrate at pH* 7.4. There appears to be an equilibrium between free citrate, dinuclear species [Bi(citrate)₂Bi]²⁻ and multinuclear bismuth citrate clusters at physiological pH values. The solid-state structure of the anti-ulcer drug, ranitidine bismuth citrate may be closely related to that of Na₂[Bi₂(citrate)₂·7H₂O] in view of the similarity in their chemical compositions (Bi : citrate = 1 : 1), crystallization conditions (ca. pH 4), and solid-state ¹³C NMR spectra.¹³³ Second coordination sphere interactions between coordinated citrate and ranitidine have been detected by ¹H NMR.¹³⁰

Both antimony and bismuth form stable complexes with the tripeptide glutathione (GSH) with a stoichiometry [Bi(GS)₃] or [Sb(GS)₃]. The rate of uptake of these metals into red blood cells and complexation with intracellular glutathione as determined by spin-echo ¹H NMR, is rapid for Sb³⁺ (minutes) and relatively slow for Bi³⁺ (hours).^{134,135} Strong binding of Sb³⁺ to trypanothione [T(SH)₂] was chemically characterized for the first time by ESI-MS spectrometry and NMR spectroscopy. In contrast to the glutathione complex, each Sb³⁺ coordinates to only one T(SH)₂ with two sulfurs being provided from Cys residues and probably an oxygen from water.¹³⁶

Binding of bismuth to human transferrin was unexpectedly strong.^{137,138} The uptake of Bi³⁺ by apo-transferrin from bismuth citrate complexes is very slow (hours at 310 K) and occurs in at least two steps, whereas transfer from bismuth nitrilotriacetate is rapid (min). ¹³C NMR suggests that bismuth binds to transferrin along with carbonate (CO₃²⁻) as the synergistic anion, which is similar to Fe³⁺. Binding of Bi³⁺ occurs preferentially to the C-lobe of transferrin. This order of lobe-loading has been confirmed by 2D [¹H, ¹³C] heteronuclear multiple-quantum coherence (HMQC) NMR studies using recombinant ε-[¹³C]Met-hTF (ca. 0.3 mM) in which all Met residues are enriched with ¹³C at the -SCH₃ group. The changes in shift of the ¹H and ¹³C NMR resonances of Met can be used not only as a probe for determining the order of lobe-loading of transferrin with metal ions, but also as fingerprints of conformational changes induced by Bi³⁺ and other metal ions. Bi³⁺, Fe³⁺, Ga³⁺ and Al³⁺ probably induce similar conformational changes in hTF, since the changes in shifts of SCH₃ resonances (Met) are almost identical.¹³⁹ Due to the ¹³C labeling of Met and the sensitivity enhancement obtainable by inverse detection, the possible metal binding (e.g., Bi³⁺) to transferrin (ε-[¹³C]Met-hTF) can readily be detected in the presence of large excess of other proteins and even in blood plasma by 1D and 2D [¹H, ¹³C] NMR spectroscopy.¹⁴⁰ Transferrin was found to be a potential mediator for Bi³⁺ transport in blood plasma, which may have implications for the mechanism of neurotoxicity of Bi³⁺ drugs.

6 SUMMARY

NMR spectroscopy is one of the most powerful techniques for the study of interactions of metallodrugs with molecules of biological importance. The chemical shifts of some nuclei such as ¹⁹⁵Pt are sensitive to either the oxidation state or to coordination sphere and provide information on the binding site of the metallodrug-biomolecule complex. With the development of NMR techniques and currently available high-fields (e.g., >17 T), more information is expected to be obtained from NMR experiments. The recent success of ⁶⁷Zn NMR in the study of a metalloprotein may shed light on other biologically relevant quadrupolar nuclei.¹⁴¹ The use of inverse detection of ¹³C or ¹⁵N (e.g., 2D HSQC, HSQC-TOCSY, HSQC-NOESY) together with isotopically-labeled metallodrugs or biomolecules, allows studies to be conducted at physiologically relevant concentrations. The structures and dynamics of metallodrug-biomolecule complexes which have been investigated by 1D and 2D homo- and hetero-nuclear NMR techniques will continue to be an important field of study. Theoretically, drug discovery of inorganic compounds can also be screened based on structure-and-activity relationship NMR (SAR-NMR)¹⁴² and we have demonstrated that metallodrug binding to the 80 kDa protein (transferrin) can readily be followed.^{139,140} Screening the binding of inorganic compounds to larger proteins and enzymes should now be possible by the transverse relaxation-optimized spectroscopy (TROSY) experiment.¹⁴³ The combination of NMR techniques with chromatography (LC-NMR and HPLC-NMR) should be a powerful method for the identification of novel metallodrug metabolites.¹⁴⁴

1 INTRODUCTION

Mitochondrial cytochrome *c* is a small (12.4 kDa), soluble, basic protein that mediates single electron transfer between integral membrane protein complexes in the respiratory chain of eukaryotes.¹ Because of its stability, solubility and ease of preparation, cytochrome *c* has become one of the most thoroughly studied proteins, not only in terms of its biological function but also as a model system for studies of, for example, protein folding,² interprotein electron transfer,³ molecular recognition,⁴ antigenicity,⁵ and protein dynamics (see below). As one of the first classes of proteins subjected to structural analysis by X-ray crystallographic techniques, a number of high-resolution models for the structures of *c*-type cytochromes have emerged.⁶ These and other detailed structural studies have provided the basis for comprehensive evaluation of hypotheses concerning the fundamental nature of the electron transfer processes in proteins.⁷ The mitochondrial cytochromes of the *c* type have been extensively examined by NMR methods. ¹H NMR based studies have a long history and find roots in the classic studies of Kowalsky,⁸ Gupta and Redfield,⁹ and McDonald and Philips.¹⁰

2 RESONANCE ASSIGNMENTS

Early ¹H resonance assignment studies were led by the pioneering work of Williams, Moore, and co-workers¹¹ and by Wüthrich and co-workers.¹² Much of that work focused on the assignment of the ¹H resonance of the reduced, or ferrous, form, ferrocytochrome *c*, in which the heme iron is diamagnetic. For ferrocytochrome *c*, the ¹H chemical shifts are restricted to between −4 and 11 ppm. In the efforts dealing with the ferric form, ferricytochrome *c*, where the low spin- $\frac{1}{2}$ iron provides an intrinsic paramagnetic perturbation, the initial efforts concentrated on paramagnetically shifted ¹H resonances dispersed in the chemical shift range of −40 to +40 ppm. In the early 1980s, the approaches to the resonance assignments became decidedly more aggressive and comprehensive. The work of Williams, Moore, and co-workers is particularly noteworthy for their application of a wide variety of analytical

NMR techniques to what was then a seemingly impenetrable resonance assignment problem. In their initial ground-breaking efforts, these investigators were able, without the benefit of two-dimensional NMR techniques or extremely high magnetic fields, to assign a significant fraction of the side-chain ¹H resonances of both reduced and oxidized cytochrome *c* from a variety of species. Approaches used included comparison of ¹H NMR spectra of homologous cytochromes *c*, structure dependent interpretations of chemical shifts, and steady state and transient nuclear Overhauser effects (NOEs) and spin decoupling. Wüthrich and co-workers used a variety of NOE-based methods, including two-dimensional NOESY spectra, to characterize the role of axial ligand geometry on the setting of the redox potential of *c*-type cytochromes. Comprehensive ¹H resonance assignments were not completed until the work of Wand and co-workers with the essentially complete assignment of the ¹H NMR spectrum of the horse protein in both redox states.^{13–15} Efforts with the reduced protein led to the formalized NOE-based pattern recognition method for analysis of ¹H NMR spectra of proteins termed the ‘main chain directed resonance assignment strategy’.¹⁶ These studies also resulted in the extensive characterization of the backbone conformation of the protein in its two redox states. The resonance assignments of the protein were extensively cross correlated by use of two-dimensional NOESY spectra of mixtures of the two redox states.¹⁷

Analysis of the carbon spectrum of cytochrome was initiated with the natural abundance studies done by Oldfield and Allerhand¹⁸ and subsequently carried forward by Oldfield and others.¹⁹ NMR studies using both ¹³C and ¹⁵N have been limited by the inability to cost-effectively isotopically enrich eukaryotic *c*-type cytochromes by recombinant DNA methods. Chemical modification of the protein has also allowed introduction of NMR active isotopes of fluorine²⁰ and iron.²¹

3 STRUCTURAL ANALYSIS

Focused structural studies have paralleled progress in the solution of the resonance assignment problem. Early work centered on structural issues regarding heme pocket packing¹¹ and axial ligand geometry,¹² which could be approached directly as the reporter ¹H resonances were generally well resolved. Particular emphasis was placed on comparisons of the coordination geometry at the heme iron and the electronic structure of ferric heme in homologous cytochromes *c*.¹² Detailed and relatively comprehensive structural analysis began with the characterization of the heme *g* tensor in the oxidized state and its use in detecting diamagnetic chemical shift changes (i.e. structure change) induced by a change in redox state.^{22–24} These studies suggested the presence of localized and potentially significant structural differences between the two redox states, in contrast to the only subtle structural differences observed in models of the crystal structures of homologous cytochromes *c*. A more recent application of this approach combined both ¹H and ¹³C chemical shift changes upon a change in redox state, allowing for a more explicit separation of paramagnetic and diamagnetic chemical shift effects.²⁴ Other NMR-based studies, primarily analysis of chemical shift perturbation and local NOE patterns, have also provided indications that the structure of cytochrome *c* is somewhat sensitive to conditions of salt type and concentration.^{25,26}

The recent controversy surrounding the issue of the relative importance of the specific σ -bond pathway model for electron tunneling through the protein intervening between electron transfer donor and acceptor moieties, such as heme, raises the need for comprehensive structural detail under conditions where most experimental data on interprotein electron transfer chemistry are available, i.e. in solution under low ionic strength conditions. Truly comprehensive structural analysis of a mitochondrial *c*-type cytochrome has only recently been reported.^{27–29} Using a variety of ^1H NMR-based techniques, Wand and co-workers have determined to very high precision the solution structures of reduced and oxidized horse heart cytochrome *c* by use of two- and three-dimensional ^1H NMR spectroscopy and hybrid distance geometry–dynamical simulated annealing calculations. Here, a significant limitation was the inability to label the protein with ^{13}C or ^{15}N or to use heteronuclear techniques to resolve and assign ^1H – ^1H NOEs. Nevertheless, use of three-dimensional NOESY TOCSY spectra allowed the resolution and assignment of over 1900 and 1600 NOEs for the reduced and oxidized proteins, respectively. These restraints, when combined with ϕ torsion angle restraints determined by analysis of amide NH–C- α H J coupling constants, resulted in a family of structures which show all-residue rms deviations of the main chain atoms from the mean structure of better than 0.047 nm and 0.037 nm for the reduced and oxidized protein, respectively.

Stereo pairs of the backbone of the refined average structure of horse cytochrome *c* in each redox state are represented in Figures 1 and 2 as ribbon drawings.

These highly refined structures reveal several internal and surface features that may be important in the function, stability, and dynamical behavior of this protein. Some of these features have been noted previously with homologous proteins, while others have not. For example, a previously undocumented surface reorganization involving Ile81 appears to function as a molecular recognition device signaling the current redox state of the protein. On the main chain, the reduced protein displays unusual 3_{10} to α -helical transitions in the two of the three main helical segments of the protein. This leads to a bifurcated peptide carbonyl in the core of each helical segment.

In sum, the determination of the high-resolution models of the solution structures of oxidized and reduced cytochrome *c* by methods based on NMR has allowed a detailed comparison to be made between the solution structure of the protein in its two redox states and the corresponding structures of the

Figure 1 Ribbon diagram of the refined average solution structure of horse ferrocytochrome determined using NMR-based methods.²¹ Drawn with the computer program MOLSCRIPT⁴⁰

Figure 2 Ribbon diagram of the refined average solution structure of horse ferricytochrome determined using NMR-based methods.²² Drawn with the computer program MOLSCRIPT⁴⁰

homologous tuna protein in the high salt crystalline state. The latter structures have been used extensively in theoretical studies of solvent reorganization energies and other electron transfer parameters. An observed variance of the crystal structures with the low salt solution structures could therefore potentially be quite significant. Indeed, several differences have been detected between the solution and crystalline structures of the protein in both redox states.

Several detailed crystallographic studies of the structure of *c*-type cytochromes have revealed the presence of structural, deeply buried water molecules, which are apparently conserved across the cytochrome *c* family of proteins. In particular, one water molecule, located at a triad involving the side chains of residues Tyr67, Asn52 and Thr78 in the horse protein, has been suggested to be intimately linked to the setting of the redox potential of the heme. It is of considerable interest, therefore, to note that the aromatic ring of Tyr67, in both redox states, undergoes rotations on the millisecond timescale (see below). This necessarily raises several concerns about the residence time or even presence of water at this location in the protein under solution conditions. Similar comments can be made about the locations of the other three conserved structural water molecules found in the crystal structures of cytochrome *c* where there is considerable structural perturbation brought on by aromatic rings flipping at rates that are fast on the NMR chemical shift timescale. The existence of structural water in the interior of the solution structures of both oxidized and reduced horse heart cytochrome *c* has also been demonstrated using ^1H NMR spectroscopy. Using pseudo-three-dimensional NOESY TOCSY spectra, Qi and co-workers²⁹ have located six and five water molecules with residence times greater than a few hundred picoseconds in ferrocytochrome *c* and ferricytochrome *c*, respectively. Two water molecules are located in the heme crevice (see Figure 3). One of the water molecules is found to undergo a large change in position upon a change of oxidation state. Both these observations indicate that buried structural waters in the heme crevice, via microscopic dielectric effects, probably play a significant role in the setting of the solvent reorganization energy associated with electron transfer.

4 DYNAMICS AND STABILITY

The dynamics and stability of both redox states of cytochrome *c* have been probed extensively by NMR methods. Beginning with the earliest library of ^1H resonance

Figure 3 Heavy atom skeleton of several of the amino acid side chains surrounding one of the structural water molecules found in the interior of horse ferricytochrome *c*. Shown is the refined average structure derived from a family of highly refined structures having an average rms deviation from the mean structure of 0.051 ± 0.007 nm, for the main chain heavy atoms, and 0.106 ± 0.007 nm for all heavy atoms.²⁷ Details of the refinement of the structural model for oxidized horse cytochrome *c* are reported elsewhere.²⁷ Shown are the side chains of Asn52, Tyr67, Thr78, and the heme. Also shown are the amide NH groups of Lys79, Asn52, and Gly77, which provide NOE-based distance constraints to the water molecule. This particular water molecule is restrained in the model by five direct NOE-based restraints (indicated by white lines). Drawn with the computer program RIBBONS⁴¹

assignments, Moore, Williams, and co-workers have demonstrated that reduced cytochrome *c* is remarkably stable to both extremes of pH and temperature, maintaining extensive structure over pH 4–12 and from 4 °C to nearly 100 °C at pH 7.0.³⁰ The oxidized protein is somewhat less stable to extremes of pH and temperature.³¹ The pH induced isomerization of cytochrome *c* has been studied extensively by ¹H NMR and is associated with a pK_a of approximately 9.5. At low pH, a so-called ‘molten globule state’ of the protein is achieved, which has been indirectly characterized by ¹H NMR methods and hydrogen exchange.³² In addition to the characterization of the gross behavior of the protein, NMR has provided a great deal of insight into the activated processes leading to local motion arising from local instabilities. Large variation of the activation barriers associated with the flipping of phenylalanine and tyrosine aromatic rings about the β – γ rotation axis has been examined extensively by means of both one-³⁰ and two-dimensional methods.¹² Indeed, while several aromatic rings are in fast exchange at temperatures below 20 °C, the ring of Tyr67 remains in intermediate exchange on the NMR chemical shift timescale, even at temperatures above 70 °C.

The rates of hydrogen exchange of the backbone amide hydrogen atoms of the protein have also been used as a sensitive measure of changes in local stability and dynamics.³³ Early observations of amide hydrogen exchange by NMR methods immediately indicated a wide range of local stabilities and dynamics on the main chain of the protein in the two redox states. With the completion of the ¹H resonance assignments of the backbone amide hydrogen atoms of the protein in its two redox states, it should be possible to use hydrogen exchange to pinpoint those parts of the protein that are functionally involved in setting of the redox potential of

the heme, to identify the temporal relationships of hydrogen bonding during folding of the protein, to characterize non-native states of the protein, to identify the interaction surface in the complex with an antibody, and so on. With regard to local stability and dynamics, the hydrogen exchange data indicate a huge range of local equilibrium stabilities of the secondary structure hydrogen-bonding networks of the amino and carboxyl terminal helices, for example.^{34,35}

5 COMPLEXES

The central role of cytochromes in electron transfer processes in general and in oxidative phosphorylation in mitochondria in particular has resulted in cytochrome *c* being the focal point of a large number of physiochemical investigations of interprotein electron transfer. Unfortunately, the main biological redox partners of cytochrome *c* are large, membrane-associated proteins, and have thus far not been subjected to direct investigation of their complexation with cytochrome *c* by solution NMR methods.

Two heterologous protein complexes involving cytochrome *c* have been studied in some detail by NMR methods. One is the complex formed between cytochrome *c* and cytochrome *b*₅. Though cytochrome *b*₅ is not a physiologically relevant redox partner of cytochrome *c*, their complexation and electron transfer properties have been used as a model system with which to probe the underlying physical issues of interprotein electron transfer. Burch and co-workers³⁶ have reported the one-dimensional ¹H and ¹³C spectra of this complex and have noted only modest changes in the spectra. These authors attribute the subtlety of the spectral perturbation to an interaction domain which is primarily electrostatic and somewhat dynamic. A complete structural characterization of this complex by either NMR or crystallographic methods remains to be carried out. The second complex that has been extensively characterized by NMR methods is that between cytochrome *c* and cytochrome *c* peroxidase, a physiologically relevant complex. Satterlee and co-workers have studied this complex extensively.³⁷ One-dimensional NOE experiments combined with chemical shift perturbations proved valuable in the selective and efficient characterization of the protein–protein interface of this complex. However, as with the cytochrome *c*–cytochrome *b*₅ complex discussed above, the cytochrome *c* peroxidase–cytochrome *c* complex has not been defined comprehensively by NMR methods and remains a significant challenge of great biological significance.

The use of cytochrome *c* as a model protein for studying protein mediated electron transfer has resulted in the characterization of its interaction with a variety of inorganic complexes.³⁸ In addition, the interaction of cytochrome *c* with polyanions such as phosphate and adenosine triphosphate has also been examined. The latter has been argued to represent a feedback interaction point for the oxidative phosphorylation pathway of energy metabolism. These kinds of study are necessary to gain insight into the structural and electronic changes which govern the interaction and transfer of electrons between proteins. In particular, the balance between hydrophobic and electrostatic interactions can be probed by studies of the structural changes that occur upon changes in salt.^{25,26}

A most interesting interaction of cytochrome *c* is that of binding to membrane or membrane mimetics. Though

extensively studied by other techniques, solution NMR methods have yet to be brought fully to bear on the characterization of the effects of membrane association on the structure of cytochrome *c*. With the exception of early work by Brown and Wüthrich,³⁹ which concentrated on the lipid portion of a vesicle–cytochrome *c* interaction, solution NMR methods have been used little in the characterization of the structural perturbations of the protein brought about by its association with a membrane-like surface. This promises to be a rich area of future investigation and will help complete the long history of the NMR-based description of the structure, dynamics, and function of this biologically critical protein.

1 INTRODUCTION

Myoglobin, (Mb) is a small (15–18 kDa) protein containing a heme [Figure 1(a)], widely distributed in the animal kingdom, whose role is to store O₂ in muscle.¹ The reversible binding of O₂ by heme iron is one of the simplest in biochemistry, and intense study of both the reaction and structure of Mb have made it a major test case for the detailed elucidation of the relationship of function to structure and/or dynamics. Mb exhibits a remarkably conserved globular folding pattern of eight helices, A–H, with the heme wedged between helices E–F, in spite of the large variation in sequence and ligand affinity/dynamics. The only completely conserved residues are the axial (proximal) ligand His F8 (histidine) (position 8 on helix F), and a Phe CD1 (phenylalanine) in contact with the heme edge (position 1 of loop between helices C, D). The variation in ligation properties is attributed to the nature of the E helix residues in the distal pocket, in particular those at positions E7 and E11. To favor binding O₂ over the toxic adventitious CO, the protein exerts a stabilization by distal hydrogen bonding to the polar and bent Fe(II)O₂ unit [Figure 1(b)], and a destabilization by steric tilting of the nonpolar, linear Fe(II)CO unit [Figure 1(c)], which prefers to bind normal to the heme. The distal H-bond to O₂ [Figure 1(b)] is provided by His E7 in the large majority of mammalian Mbs, and in rare cases by glutamine (Gln); the latter residue is more common in invertebrate Mbs, and several have nonpolar E7 residues.² The E11 residue is invariably nonpolar [valine, isoleucine (Val, Ile)]. Both structural and functional properties of Mb are shared with hemoglobin, Hb, the related protein involved in O₂ transport, which is often found in oligomerized forms (see *Hemoglobin*).

Physiological active Mb has a ferrous, Fe(II), heme, designated Mb^{II}, which is high-spin in unligated or deoxy Mb^{II} and diamagnetic in the CO and O₂ ligated forms:

Mb^{II}O₂, however, is relatively unstable with respect to autoxidation to ferric Mb or metMb, designated Mb^{III}. While Mb^{III} is not a physiologically functional form, the electronic/magnetic and ligation properties of these necessarily paramagnetic variants serve as extraordinarily sensitive probes of important structural controls of function.¹ At acidic to

neutral pH, high-spin Mb^{III} may possess a vacant sixth site or ligated H₂O, and readily reacts with small anionic ligands, X[−], according to:

2 ¹H NMR SPECTRAL PROPERTIES

The active site chemical shifts for diamagnetic Mb^{II}CO and Mb^{II}O₂, δ(dia), are dominated by the large ring current of the heme, δ_{rc},

$$\delta(\text{dia}) = \delta_{\text{pep}} + \delta_{\text{rc}} \quad (3)$$

where δ_{pep} is the peptide chemical shift as influenced by the secondary structure. The remainder of the derivatives are all paramagnetic, for which the observed shift, δ(para), is given by

$$\delta(\text{para}) = \delta_{\text{dia}} + \delta_{\text{hf}} \quad (4)$$

where δ_{dia} contains all diamagnetic influences (see *Amino Acids, Peptides and Proteins: Chemical Shifts*). For practical purposes, δ_{dia} in equation (4) can be substituted by the value in equation (3). The hyperfine shift, δ_{hf}, has the two components:³

$$\delta_{\text{hf}} = \delta_{\text{con}} + \delta_{\text{dip}} \quad (5)$$

where the contact contribution, δ_{con}, reflects delocalized spin density onto the ligand and the dipolar contribution, δ_{dip}, reflects anisotropy of the paramagnetic susceptibility tensor, χ, and is given for proton *i* by:

$$\delta_{\text{dip}}^i = \Sigma^q \Delta \chi_q G F_q^i R(\alpha, \beta, \gamma) \quad (6)$$

where *q* = axial, rhombic, *GF_q* are geometric factors of proton *i* in iron-centered X-ray coordinates, and *R*(α,β,γ) are the Euler rotation angles that convert the iron-centered X-ray to the magnetic coordinate system [*x',y',z'* → *x,y,z* in Figure 1(a), 1(d)], where the susceptibility tensor, χ, is diagonal. Lastly, the paramagnetic influence on relaxation for proton *i* can be related to proximity to the iron, *R_{Fe}*, via:

$$T_1^{-1} \propto R_{\text{Fe}}^{-6} \quad (7)$$

The ¹H NMR spectra for the four readily accessible oxidated/spin states of Mb are illustrated in Figure 1(e)–(h). All paramagnetic forms exhibit hyperfine shifts and relaxation which increase with *S*, with the resolved (hyperfine shifted) signals observed outside the δ 0–10 ppm range necessarily arising from the active site.⁴ The assignment of the largely overlapped resonances in diamagnetic MbCO (and MbO₂ when stable) are carried out by standard 2D methods, although heteronuclear labeling is necessary for a complete assignment because of the size of the protein.^{5,6} In the paramagnetic derivatives, the initial assignments^{4,7} were restricted to the

Figure 1 (a) Structure of the heme, as viewed from the distal side, with substituents M (methyl), V (vinyl), and P (propionate) at positions 1–8. The approximate position of distal residues E7, E11, and Phe CD1 in Mb are indicated. Edge-on views of the heme with; (b), iron(II)-coordinated O_2 that serves as a hydrogen-bond acceptor to the distal residue designated B–H; (c), iron(II)-coordinated CO which is tilted from the preferred heme normal by distal steric interactions (possibly with BH), but with no hydrogen bond with BH; and (d), iron(III)-coordinated CN^- , which is both tilted from the preferred heme normal due to steric interaction (like CO), and serves as a hydrogen-bond acceptor to the distal BH. The notation x', y', z' represents an iron-centered symmetry coordinate system with z' normal to the heme, and x, y, z are the coordinates in which the paramagnetic susceptibility tensor, χ , is diagonal (magnetic coordinate system). The coordinates x, y, z are related to x', y', z' by the Euler rotation angles α, β, γ so that $(x', y', z')R(\alpha, \beta, \gamma) \rightarrow (x, y, z)$. The quantity β defines the magnitude of the z axis tilt [shown in (d)], α defines the direction of tilt of the major magnetic or z axis tilt [shown in (a)], and the rhombic or in-plane magnetic axes, x, y , are related to x', y' by the angle $\kappa \sim \alpha + \gamma$ [as shown in (a)]. The 360 MHz 1H NMR spectra at 25°C of sperm whale Mb in different oxidation/spin states are illustrated in: (e) for diamagnetic ($S = 0$) $Mb^{II}CO$ in 2H_2O , pH = 7.6; (f) for paramagnetic ($S = \frac{1}{2}$) $Mb^{III}CN$ in 2H_2O , pH = 8.6; (g) for paramagnetic ($S = 2$) deoxy Mb^{II} in 1H_2O , pH = 8.2; and (h) for paramagnetic ($S = \frac{5}{2}$) $Mb^{III}H_2O$ in 2H_2O , pH = 6.5. The assigned signals are labeled M_i (methyl), H_i (single proton), where i is the position on the heme ($i = 1–8$), or the helical or loop position of an amino acid residue

heme (via isotope labeling) and the labile ring protons of the proximal F8 and distal E7 His [via paramagnetic relaxivity, see equation (7)]. Later, steady-state NOEs and 2D experiments, appropriately tailored for rapidly relaxed resonances, were shown to provide the necessary assignments in all derivatives.⁸

The most informative 1H NMR data on Mb have resulted from comparative studies on either crystallographically characterized natural genetic variants, i.e. sperm whale and the sea hare *Aplysia limacina*, Mbs, or synthetic point mutants of a given Mb. Moreover, the wealth of information in the hyperfine shift, the enhanced resolution it imparts to active site residues, as well as the unique ability to detect directly the distal labile proton involved in H bonding to the ligand, have resulted in an emphasis on the 1H NMR study of paramagnetic Mb derivatives.^{4,7} In particular, $Mb^{III}CN$ is a valuable model

for functional Mb because the ligand bond polarity makes it a probe for the distal H-bonding interaction of $Fe(II)O_2$, while the tilt of the preferred linear $Fe(III)CN$ unit normal to the heme [Figure 1(d)] will sense the distal steric influences that would affect the $Fe(II)CO$ unit. Hence, primarily results on paramagnetic derivatives will be discussed which provide unique information on distal H-bonding and the steric influence on the bound ligand [i.e. $Fe(III)CN$ in Figure 1(d)]; early results have been summarized by Morrow and Gurd.⁷

3 STUDIES ON DIAMAGNETIC Mb

Because of its stability,¹ most 1H NMR studies have been carried out on $Mb^{II}CO$ [spectrum in Figure 1(e)], whose

solution structure was found to be essentially the same as in the crystal;⁵ the prominently resolved upfield ring-current-shifted Val E7C- γ H₃ provided one of the first resolved protein ¹H NMR signals.⁷ Detailed assignment of titrating residues in sperm whale MbCO has provided important tests for theoretical models for pKs.^{9,10} Comparison among several human Mb^{II}CO distal point mutants have shown that structural changes are localized to the perturbed residues.¹¹ The signals for enriched ⁵⁷Fe and ¹⁷O in bound CO have also been detected (see *Chemical Shifts in Biochemical Systems*).¹² Mb^{II}O₂ has been much less studied because of its instability toward autoxidation to Mb^{III}.

4 STUDIES ON PARAMAGNETIC Mb

4.1 Electronic Structure

Information on the electronic structure is derived directly from the contact shift.^{3,4} In high-spin Mb^{II} and Mb^{III}, magnetic anisotropy, and hence the dipolar shifts, are relatively small.¹³ Therefore, the dominant contact shift dictates that the strongly hyperfine-shifted and resolved signals arise from the iron-coordinated heme and axial His, which has been amply confirmed by detailed assignments.⁴ The ⁶A ground state for Mb^{III} results in contact shifts [Figure 1(h)] which are relatively insensitive to protein environment for a given ligation state,^{4,13} but can serve as empirical probes to determine whether a water molecule is axially coordinated [spectrum in Figure 1(h)]. The heme contact shifts for deoxy Mb^{II} [Figure 1(g)] are very sensitive to the protein environment,⁴ probably because of two contributing orbital states with different spin-delocalization patterns.¹⁴ The axial His F8 contact shifts in high-spin Mb^{II}, on the other hand, are dominated by σ bonding with d_{z²}. The imidazole ring NH shift, identified in the δ 60–90 ppm window by comparing ¹H₂O and ²H₂O spectra [spectrum in Figure 1(g)], serves as a sensitive probe for axial bond strain,⁴ which has been extensively applied to deoxy Hb (see *Hemoglobin*).

The presence of a single unpaired spin in low-spin ($S = \frac{1}{2}$) iron(III) allows direct interpretation of the dominant contact shifts in terms of iron–porphyrin bonding.¹⁵ The observation of characteristic π contact shifts for free hemin confirmed the E rather than A orbital ground state. In the free hemin, d_{xz}, d_{yz}, which interact solely with a pair of *trans*-pyrroles, respectively, are essentially degenerate and are fractionally occupied by an unpaired spin, giving rise to comparable contact shifts for the heme methyls of the four pyrroles.¹⁵ Within Mb^{III}CN, however, the d_{xz}, d_{yz} degeneracy is lifted by the rhombic field of the protein, with the lone spin in the resulting orbital

$$\Psi = (\cos^2 \kappa) d_{xz} - (\sin^2 \kappa) d_{yz} \quad (8)$$

with κ locating the rhombic axes [$\kappa = \sim \alpha + \gamma$ in equation (6) and Figure 1(a)]. The angle κ reflects primarily the orientation of the axial His F8 imidazole orientation relative to the heme.^{13,15} Hence, large 1-CH₃ and 5-CH₃ (or 3-CH₃ and 8-CH₃) contact shifts are observed⁴ [spectrum in Figure 1(e)] for His F8 oriented along pyrroles B, D (or A, C) in Figure 1(a). The characteristic pattern in heme contact shifts that reflects heme orientation relative to the His F8 provided the first evidence for the now generally observed phenomenon of heme orientational disorder about the α, γ -*meso* axis.¹⁶

4.2 Distal Hydrogen Bonding

The combination of large δ_{dip} [equation (6)] and significant paramagnetic relaxation [equation (7)] generally resolves and allows identification¹⁷ of the heme pocket labile protons in Mb^{III}CN.^{17–20} The detection of an isotope effect on heme contact shift, which is uniquely traceable¹⁷ to the assigned distal side-chain NH, provides direct proof for the existence of the H bond to bound cyanide [shown in Figure 1(d)]. The H-bonding proton has been demonstrated to arise from the side chain of the E7 residue, His in sperm whale¹⁷ and Gln in elephant,¹⁸ but Arg E10 in *Aplysia*¹⁹ and a sperm whale double mutant²⁰ Mb^{III}CN. For high-spin Mb^{III}, a strong solvent isotope sensitivity of the heme contact shift was shown to reflect the presence of a distal donor and acceptor H bond in Mb^{III}OH and Mb^{III}H₂O, respectively, which accounts for the affinity of these ligands at different pH values.²¹

4.3 Distal Steric Influence on Ligand Tilt

The necessarily dipolar shifts for the noncoordinated residues in the active site of an Mb complex with significant paramagnetic anisotropy can serve not only as important auxiliary constraints (in addition to NOEs) for determining active site structures,^{13,18–20,22,23} but also allow the determination of the orientation of the paramagnetic susceptibility tensor, χ , in the molecular framework. The largest magnetic anisotropy for Mb is exhibited by low-spin Mb^{III}CN, where the out-of-plane g_z value is much larger than the two in-plane values; outside the protein matrix, the g_z value is normal to the heme. However, since cyanide is the strongest ligand in Mb^{III}CN, distortion of the Fe(III)CN unit from the heme normal will result in tilting of the major magnetic axis from the normal (z') by an angle β in Figure 1(d), and in a direction whose projection on the heme plane is defined by α [Figure 1(a)] in the Euler rotation $R(\alpha, \beta, \gamma)$ in equation (6).¹³ The value of δ_{dip} for nonequivalent nuclei provided by 2D NMR analysis of Mb^{III}CN, together with the iron-centered X-ray coordinates for any derivative of Mb, allows a least-square search that uniquely yields $\Delta\chi_{\text{ax}}$, $\Delta\chi_{\text{rh}}$, and the three Euler angles α , β , γ . 2D NMR assignments of sperm whale and *Aplysia* Mb^{III}CN have yielded orientations of the magnetic z axis that are consistent with the crystallographically-determined Fe(III)CN units.^{13,19} Moreover, it was shown that the anisotropy and Euler angles could be uniquely determined using experimental ¹H NMR data and X-ray coordinates only for the residue on the proximal side of the heme, for which both δ_{dia} and the coordinates for GF_q in equation (6) can be expected to be highly conserved in distal point mutants.¹³ The latter conclusion allows the investigation of the influence of specific distal residues by site-directed mutagenesis in providing H bonding to, or sterically tilting of, the bound ligand.

Substitution of the His E7 by a glycine (Gly) or Val in Mb leads to an essentially unchanged Fe(III)CN tilt from that in WT ($\beta \sim 15^\circ$), but with a direction (α) rotated toward the vacancy created by removal of the tilting imidazole group²² [$\alpha = 0 \rightarrow -40^\circ$ in Figure 1(a)]. Hence, contrary to the standard textbook example, the distal His does not cause ligand tilt in Mb^{II}CO, but does determine the direction of the tilt. On the other hand, decreasing the steric bulk of the E11 residue by the substitution of WT Val $\rightarrow$ alanine (Ala) leads to a significant

decrease in tilt magnitude but not direction.²³ The effect of double mutants at both the E7 and E11 position showed that the influence on tilt magnitude/direction of the individual residues is approximately additive. Once the magnetic axes have been determined for an Mb^{III}CN distal point mutant based on the 2D NMR assigned δ_{dip} and the proximal δ_{dia} and X-ray coordinates, the δ_{dip} for the substituted distal residue can be analyzed by searching for the orientation(s) of the distal residue(s) that optimally account for the δ_{dip} [as well as iron-induced relaxivity, via equation (7), and the more conventional NOE constraints]. Detailed studies have been carried out on the His E7 $\rightarrow$ Val Mb^{III}CN mutant,²² which showed that lateral movements of the E helix by ~ 0.8 Å and of Phe CD1 by 0.5 Å, each toward the iron, result in filling the void resulting from the reduced bulk of the E7 side chain.

In the case of sea hare *Aplysia* Mb, O₂ binding indicates a distal H-bound donor, despite the fact that it possesses an E7 Val. Determination of the magnetic axes¹⁹ for *Aplysia* Mb^{III}CN allowed a quantitative description of the distal pocket which showed that an arginine (Arg) at helical position E10 [occupied by a threonine (Thr) in sperm whale Mb] orients into the heme pocket and provides a H bond to the bound CN⁻ [and by inference, bound O₂ in Mb^{II}O₂]. The orientations of the distal residues determined from the dipolar shifts are essentially the same as those found in a parallel crystal diffraction study of that protein. Subsequently, it was possible to construct a double mutant sperm whale (His E7 $\rightarrow$ Val, E10 Thr $\rightarrow$ Arg) Mb to make a synthetic sperm whale Mb where the distal H bond is provided²⁰ by the Arg E10 with orientation similar to that in *Aplysia* Mb. The direction of tilt of the FeCN unit in E7 Val/E10 Arg Mb^{II}CN differs from that on the E7 Val single mutant in a manner indicative of attractive H bonding between Arg E10 and the bound ligand in the former protein.

1 INTRODUCTION

The nonheme iron proteins listed in the Table of Contents constitute a representative sampling of a continually expanding class whose iron sites have a diverse range of structure and function. All of the proteins described in this article contain a nonheme mono- or diiron active site with O, N, or S ligands provided by amino acid side chains of the protein and/or by substrates. All such proteins for which ^1H NMR studies of the iron sites have been published through to the end of 1993 are included. Iron–sulfur proteins are dealt with in another article in this Encyclopedia and are, therefore, not included here (see *Iron—Sulfur Proteins*).

With the recent expansion and diversity of known nonheme iron proteins has come a need for techniques to probe the structural and electronic factors which affect the reactivities of these iron sites. Starting in about 1982, ^1H NMR was shown to be a useful probe of these sites, and its usage has expanded since that time along with the number of proteins and advances in NMR technology. These studies were pioneered and developed largely by Que and co-workers.

The paramagnetism of the iron sites in these proteins has not discouraged the application of ^1H NMR. On the contrary, the large chemical shifts and altered ^1H relaxation times induced by this paramagnetism have provided extremely sensitive and selective probes of ligand type, coordination mode, and geometry, and have also delineated the magnetic properties of these iron sites. These insights would have been impossible without a theoretical and experimental framework for dealing with NMR of paramagnetic metal complexes.^{1,2} This framework is most extensively developed for the ^1H , and this circumstance, along with the difficulty and expense of isotopically enriching proteins in nuclei such as ^{13}C , has made ^1H the focus of NMR investigations of nonheme iron proteins up to now. Therefore, this article describes the unique information which ^1H NMR can provide about paramagnetic nonheme iron sites in proteins. Only solution NMR of paramagnetic iron sites in proteins has so far been shown to be feasible, and, therefore, the following discussion applies to aqueous solutions near ambient temperatures. In this sense NMR has been complementary to other probes of

nonheme iron sites, such as EPR and X-ray crystallography, which must use frozen solutions and crystals, respectively.

Application of theoretical principles and an experimental foundation for understanding paramagnetic effects on ^1H NMR of metalloproteins has been due largely to La Mar and colleagues and to Bertini and colleagues.^{1,2} In order to orient the reader, some relevant theoretical and practical considerations that apply to ^1H NMR of paramagnetic Fe(II) and Fe(III) complexes are summarized in this section. [The reader should consult other chapters in this Encyclopedia for information on pulse sequences, techniques for water signal suppression, etc. (see, for example, *Biological Macromolecules: NMR Parameters*). Many of the same principles discussed in *Iron—Sulfur Proteins* are equally relevant to the nonheme iron proteins discussed here.]

The extra magnetic field due to the paramagnetic transition metal ion either adds to or subtracts from the applied field at protons near the metal center. This additional field is responsible for the large high-frequency (downfield) (i.e., positive in sign) or low-frequency (upfield) (i.e., negative in sign) shifts, respectively, in NMR resonance positions relative to diamagnetic systems. The shift due to the paramagnetic center is referred to as an isotropic shift, δ^{iso} , which is the observed chemical shift minus a reference diamagnetic shift. The quantity δ^{iso} is the sum of contact (through-bond) and dipolar (through-space) contributions:

$$\delta^{\text{iso}} = \delta^{\text{con}} + \delta^{\text{dip}} \quad (1)$$

High-spin Fe(II) and Fe(III) are by far the most common oxidation and spin states found in nonheme proteins, and so far the only states examined by NMR. The singlet orbital ground state of high-spin Fe(III) normally results in only contact contributions to the isotropic shifts. The orbital angular momentum associated with the quintet ground spin state of high-spin Fe(II) in a pseudooctahedral ligand field can result in significant dipolar contributions to the isotropic shifts. The dipolar contributions arise from the magnetic anisotropy of the complex and are analogous to (but much larger than) the well-known diamagnetic ring current effects on chemical shifts of aromatic protons. The anisotropy gives rise to internal magnetic fields centered at the metal ion, which, at the position of a proximal proton, can either add to or subtract from the applied field in the NMR experiment. For a system in which the molar magnetic susceptibility, χ , is axially symmetric (i.e., $\chi_{\parallel} \neq \chi_{\perp}$), the dipolar contribution depends on the angle, θ , between the nonbonded Fe–H distance vector, r , and the principal magnetic susceptibility axis, $\chi_{\parallel}$, of the complex according to

$$\delta^{\text{dip}} = (1/3N)(\chi_{\parallel} - \chi_{\perp})(3 \cos^2 \theta - 1)r^{-3} \quad (2)$$

where N is Avogadro's number. Thus, both the magnitude and sign of the dipolar contribution are highly sensitive to the iron site geometry. The equation describing dipolar contributions to the isotropic shift contains both T^{-1} and T^{-2} temperature terms, with the latter term dominating for iron complexes.

The magnitude and sign of the contact contribution to the isotropic shift depends on the pathway of bonds and orbitals over which the unpaired spin is delocalized. Electron spin delocalization into the σ - or π -bond system of ligands to high-spin Fe(III) or Fe(II) usually occurs via ligand $\rightarrow$ metal antiparallel (i.e., opposed to the applied magnetic field) spin transfer, leaving net parallel (i.e., aligned with the applied field) spin on the ligating atom.¹ Subsequent spin delocalization through the σ -bond system of the ligand then

delivers parallel spin to the protons, which results in higher-frequency (i.e., positive in sign) contact shifts. These shifts usually drop off by roughly an order of magnitude with each intervening σ bond. Spin delocalization from the ligating atom through a ligand π system containing atom X cannot result in direct placement of unpaired spin density onto an X–H proton, since the X–H bond is orthogonal to the π system. Instead, spin polarization of the electron pair in the X–H bond results in net unpaired spin near the proton which is opposite in sign to that in the π orbital of atom X. Thus, delocalization of parallel or antiparallel spin into the X atom π orbital will result in low-frequency (negative) or high-frequency (positive) contact shifts, respectively, for the X–H proton. The spin density can alternate in sign around an aromatic ring, e.g., for a six-membered carbon ring, spin density at *ortho*- and *para*-carbon π orbitals is opposite in sign to that at the *meta*-carbon π orbitals. Furthermore, for π -spin delocalization, the magnitude of the contact contribution is not dependent on the number of intervening π bonds, but rather is a function of the relative π -electron densities on the various atoms in the π system.

Unpaired π -electron spin density on atom X can be delocalized onto X–C–H protons of methyl, methylene, or methine groups by a hyperconjugative mechanism. In this case the amount of spin delocalization depends on the torsion angle, θ_H , around the X–C bond between the long axis of the π orbital on X and the C–H bond axis, according to

$$\delta^{\text{con}} = k \cos^2 \theta_H \quad (3)$$

The proportionality constant, k , contains the product of an electron–nuclear hyperfine coupling constant for the hyperconjugative spin delocalization pathway and the magnitude of the unpaired π -spin density on X. For freely rotating groups, the averaged value, $\langle \cos^2 \theta_H \rangle$, is 0.5 (equivalent to $\theta_H = 45^\circ$). Thus, according to equation (3), the contact shift for restricted torsion angles can range from zero to twice the averaged free rotation value by the factor $2 \cos^2 \theta_H$. The sign of the delocalized spin on the X–C–H proton will be the same as that on the X atom π orbital. Therefore, for π -spin delocalization, –C–H and –H linkages to the same X atom of an aromatic ligand will have ^1H NMR contact shifts of opposite signs.

The contact contribution to the isotropic shifts of ligand protons is directly proportional to the molar magnetic susceptibility via the electron–nuclear hyperfine coupling constant. For a mononuclear high-spin Fe(II) or Fe(III) site, the contact contribution will show a T^{-1} , i.e., Curie, temperature dependence. For iron clusters, the contact contribution for an individual ligand is proportional to the molar magnetic susceptibility of the iron to which the ligand is attached, and, due to magnetic coupling between the unpaired electron spins, the susceptibility of each iron center in the cluster will not necessarily have a Curie temperature dependence. For diiron clusters (the only type encountered for the proteins discussed here) the magnetic coupling can be described by a spin Hamiltonian, $\hat{H}_{\text{ex}} = -2J S_1 \cdot S_2$, where S_1 and S_2 represent the spin states of each iron in the cluster [either $\frac{5}{2}$ for high-spin Fe(III) or 2 for high-spin Fe(II)]. Antiferromagnetic coupling is most often encountered in diiron proteins. For such coupling $J < 0$ (by the convention used here), and a ladder of spin states, $S_{\text{Tot}} = [(S_1 - S_2), (S_1 - S_2 + 1), \dots, (S_1 + S_2)]$, is obtained, with each spin state in the ladder separated from the next lower state by $2S_{\text{Tot}}J$. For antiferromagnetic coupling, the state with lowest spin multiplicity is lowest in energy, and the higher states

are thermally populated according to a Boltzmann distribution. Thus, for antiferromagnetic coupling, the molar magnetic susceptibility of each iron in the cluster, and, therefore, its ligand contact shifts, will be reduced from the values for mononuclear iron centers. The magnitude of J can be determined from least-squares fits of molar magnetic susceptibility, χ_M , versus absolute temperature, T , to the Van Vleck equation modified to account for the Boltzmann population of the spin states with J as a variable parameter. For $-J$ values less than approximately 200 cm^{-1} , nonzero states of the spin manifolds are populated in the region of room temperature. Since ligand proton contact shifts are proportional to χ_M , the temperature dependence of the contact shifts can also be used to estimate the value of J . For ^1H NMR, this method works well if, over the temperature range of the NMR measurement (10 – 60°C for most nonheme iron proteins), χ_M varies significantly (so that $\Delta\delta^{\text{con}}/\Delta T$ is large enough to be reliably measured) and nearly all spin states of the ladder are appreciably populated (so that an averaged electron–nuclear hyperfine coupling constant can be used). These requirements are satisfied for weakly coupled systems, i.e., $-J < 30 \text{ cm}^{-1}$.

For all paramagnetic metal complexes, broadening of the ^1H NMR resonances occurs due to shortening of the ^1H transverse relaxation time, T_2 , relative to a diamagnetic system. In the absence of chemical exchange, the mechanism for shortening T_2 contains contact (T_{2F}), dipolar (T_{2D}), and Curie relaxation (T_{2C}) time components such that:

$$T_2^{-1} = T_{2F}^{-1} + T_{2D}^{-1} + T_{2C}^{-1} \quad (4)$$

Usually only the dipolar and Curie relaxation components make a significant contribution in nonheme iron systems. Both T_{2D}^{-1} and T_{2C}^{-1} contribute an r^{-6} dependence to T_2^{-1} , where r is the shortest through-space Fe–H distance. Thus, protons closest to the metal center exhibit the largest NMR linewidths. An empirical result of this distance dependence for nonheme high-spin Fe(III) centers in proteins is that protons closer than 5 – $7 \text{ \AA}$ from the metal ion are often not observable by NMR, i.e., the resonances are unobservably broadened into the baseline.^{3–5} Thus, for example, His $\text{C}_\epsilon\text{H}$ (cf. Scheme 1) has not been observed by ^1H NMR when His is coordinated to Fe(III) in nonheme proteins.^{3–5} The dipolar contribution to T_2^{-1} is also a function of the electron spin moment on the metal ion, which is higher for high-spin Fe(III) [$S = \frac{5}{2}$ than for high-spin Fe(II) ($S = 2$)]. However, the magnitude

Scheme 1

of the spin moment does not by itself prevent observation of ligand resonances in either oxidation state. Finally, the dipolar contribution to T_2^{-1} is a function of τ_c , where $\tau_c^{-1} = \tau_R^{-1} + \tau_s^{-1}$, τ_R is the rotational correlation time and τ_s is the electron spin–lattice relaxation time of the paramagnetic metal ion. Depending on their relative magnitudes, either τ_R^{-1} or τ_s^{-1} can dominate τ_c^{-1} . In nonheme iron proteins, τ_s has been estimated to be 10^{-9} – 10^{-10} s for high-spin Fe(III) and 10^{-11} s for high-spin Fe(II).^{2,4} Therefore, given that $\tau_R > 10^{-9}$ s at accessible temperatures for even the smallest proteins, τ_s^{-1} should generally dominate τ_c^{-1} in nonheme iron proteins, in which case longer τ_s values should result in broader NMR resonances. In fact, some empirical observations suggest that τ_s is a major contributor to ^1H NMR linewidths in nonheme iron proteins. First, substitution of metal ions such as high-spin Fe(II) or Co(II), which have significantly shorter τ_s values than high-spin Fe(III), narrows the linewidths of isotropically shifted ^1H NMR resonances in these proteins.^{5,6} This statement also applies to diiron clusters.^{2,3} Thus, for a given distance from the metal, ^1H NMR linewidths are narrower for ligands to Fe(II) than to Fe(III) centers. Second, changing the coordination sphere around Fe(III) can affect the NMR linewidths. This phenomenon is due to a change in D , the axial zero field splitting parameter of the iron center. Larger values of D shorten τ_s , thereby narrowing the NMR resonances.⁴ One possible explanation as to why ligand NMR resonances have not yet been observed for Fe(III) transferrin is an unusually low value of D for this site (see *Transferrins*).

The contribution to T_2^{-1} due to Curie spin relaxation varies as the square of the applied magnetic field strength and is also a function of τ_R and of $[S_{\text{Tot}}(S_{\text{Tot}} + 1)]^2$. For proteins, τ_R is sufficiently long ($> 10^{-9}$ s) that increasing the magnetic field strength in order to increase sensitivity and dispersion can lead to counterproductive broadening of resonances.² For nonheme iron proteins, magnetic field strengths corresponding to a radio-frequency range of 300–400 MHz for ^1H NMR have been found to be a convenient experimental compromise between sensitivity and Curie spin relaxation effects. (The frequent use of 300–400 MHz ^1H NMR spectrometers for studies of nonheme iron proteins probably reflects commercial availability. Higher resolution spectra could undoubtedly be obtained on lower frequency spectrometers, but such spectrometers often must be homebuilt or must have the electronics upgraded.) Approximately 0.5 mL of protein solution in the millimolar concentration range is required to obtain a spectrum in a reasonable time period (i.e., several hours) near ambient temperatures. Spectra of nonheme iron proteins from 6000 to 100 000 Da have been successfully obtained under these conditions. When Curie spin relaxation affects NMR linewidth, increasing the absolute temperature T , which decreases T_{2C}^{-1} by a factor of T^{-3} , can significantly narrow the resonances, effectively increasing the sensitivity.

For isotropically shifted resonances of nonheme iron proteins, the major contributor to the longitudinal relaxation time T_1 is usually dipolar relaxation. The dipolar relaxation rate, T_{1D}^{-1} , is also a function of r^{-6} and τ_s ; therefore, T_1 measurements can be used to estimate Fe–H distances. (A rigorous treatment of the dipolar contributions to T_2^{-1} and T_1^{-1} cannot assume a point magnetic dipole centered at the iron, especially for conjugated ligands, i.e. the Fe–H distance parameter, τ , needs to be modified to account for the spin delocalization onto the ligand.²) For T_1 values

greater than 5 ms, NOE connectivities can sometimes be made for the isotropically shifted resonances. These distance estimates and connectivities can help to create a self-consistent picture of resonance assignments in a complicated spectrum. Unfortunately, the 5 ms time limit for T_1 is often not exceeded for isotropically shifted resonances of the nonheme iron proteins discussed here, which has made determinations of NOE connectivities difficult.

2 SYNTHETIC COMPLEXES

^1H NMR studies of synthetic iron complexes have been an essential adjunct to NMR studies of the proteins. The synthetic models provide (i) chemical shift ranges for the iron ligands commonly found in nonheme proteins, thereby facilitating assignments of protein resonances, and (ii) more easily measured magnetic properties, such that certain of the observed protein contact shifts and their temperature dependences can confidently be used to approximate the magnetic susceptibility of the protein iron site. Table 1 lists the chemical shift ranges observed for complexes containing analogs of the only known protein ligands to high-spin Fe(III) and Fe(II) centers in nonheme proteins, namely, tyrosine (Tyr) phenoxo, aspartate (Asp) and glutamate (Glu) carboxylato, histidine (His) imidazolyl, and cysteine (Cys) thiolato. The carbon and nitrogen atom labeling scheme used for the protons in Table 1 and throughout this article is shown in Scheme 1.

Table 1 ^1H NMR Chemical Shifts (δ) for Amino Acid Ligands in Synthetic Mononuclear Nonheme High-Spin Fe(III) and Fe(II) Complexes^a

Ligand proton	δ [Fe(III)]	δ [Fe(II)]
His:		
N δ H or N ϵ H	97–104	57–68
C δ H (N δ -ligated)	78–82	47–63
C β H ₂ (N ϵ -ligated)	19f(θ_H) ^b	7f(θ_H)
C β H ₂ (N δ -ligated)	n.a. ^c	n.a. ^c
Tyr:		
C ϵ H	–101–(–94)	–15
C δ H	85–89	11
C β H ₂	110f(θ_H)	20f(θ_H)
Asp or Glu:		
C β H ₂ or C γ H ₂	(25–125)f(θ_H)	30f(θ_H)
Cys:		
C β H ₂	(500–600) ^d f(θ_H)	200f(θ_H)
C α H	n.a. ^c	10

^aAll data are *observed* chemical shifts in ppm relative to tetramethylsilane and are taken from work published elsewhere.^{3–5,7}

^bf(θ_H) $\approx 2 \cos^2\theta_H$ and is multiplied by the observed shift (or range of shifts) found for a freely rotating methyl group, for which $2\langle\cos^2\theta_H\rangle = 1$.

^cNo published data available.

^dEstimated, cf. Que et al.⁴

The data in Table 1 serve as a reference frame for the protein data discussed below. Although the Fe(II) isotropic shifts generally have both contact and dipolar contributions, the contact contributions probably dominate most of the

isotropic shifts listed in Table 1. The contact contributions to the isotropic shifts are generally larger for ligands to Fe(III) than to Fe(II), and this observation is consistent with the larger magnetic moment of high spin Fe(III). The $f(\theta_H)$ factor indicates those shifts where the hyperconjugative mechanism of π -spin delocalization is operative. The relatively large range for the chemical shifts of Asp $C_\beta H_2$ and Glu $C_\gamma H_2$ (25–125 ppm) when coordinated to Fe(III) has been ascribed to variations in the carboxylate coordination mode, i.e., unidentate or bidentate and whether the carboxylate *syn* or *anti* lone pair coordinates to the metal. The *anti* lone pair is lower in basicity by a factor of $\approx 10^4$, which can result in a weaker Fe–O(carboxylate) bond and, therefore, a lower electron–nuclear hyperfine coupling constant. Surprisingly, there seem to be no confirmed assignments of Asp $C_\beta H_2$ or Glu $C_\gamma H_2$ 1H NMR resonances when coordinated to a mononuclear Fe(III) site in a nonheme protein. It should be emphasized that the shifts in Table 1 are for mononuclear iron centers. Magnetic coupling between iron centers in a multinuclear site can alter these shifts drastically, due to the proportionality between the contact contribution and magnetic susceptibility of the iron centers, as discussed in the Introduction.

3 CATECHOL DIOXYGENASES

Catechol dioxygenases are bacterial enzymes which catalyze the oxidative cleavage of catechols to *cis,cis*-muconic acids according to

Prior to NMR studies, the active site of catechol dioxygenases was known from other spectroscopic results to consist of a mononuclear high-spin Fe(III) center containing one or two tyrosyl and other unidentified ligands, plus one or more labile sites for substrate coordination. These enzymes were also shown to remain in the Fe(III) oxidation state throughout the catalytic cycle. Catechol 1,2-dioxygenase (CTD) was chosen for NMR studies, due to its small size (63 000 Da) and abundance relative to other catechol dioxygenases. 1H NMR has clarified two aspects of the CTD iron site: (i) the type and number of endogenous protein ligands; and (ii) the coordination modes of substrates and inhibitors. Some representative chemical shifts for isotropically shifted resonances of CTD and CTD–catecholate complexes are listed in Table 2, and representative spectra are shown in Figure 1.^{4,8}

The CTD–catecholate complexes will not turn over in the absence of O_2 and the NMR solutions of these complexes were, therefore, anaerobic. The isotropically shifted resonances observed in 1H NMR spectra of CTD can be divided into those due to endogenous ligands and those due to bound catechol substrates. Because the NMR spectra were obtained on the Fe(III) oxidation state of the enzyme, the isotropic shifts have only contact contributions. Therefore, assignments of resonances can be made by direct comparisons with shifts for the synthetic Fe(III) complexes listed in Table 1. From these comparisons it was noted that protons with an Fe–H

Table 2 Chemical Shifts for Endogenous and Exogenous Ligand and 1H NMR Resonances of Some CTD–Catecholate and Fe(III)(Salen)–Catecholate or –Phenolate Complexes^a

CTD or Fe(III)(salen) complex			
<i>Endogenous:</i>			
native CTD	75, 48	32, 24	
CTD–catechol	63, 52	35, 27, 22	
CTD–4-methylcatechol	62, 53	34, 26, 21	
<i>Exogenous (4-CH₃):</i>

^aChemical shifts in ppm at 30 °C referenced to tetramethylsilane; data from Que et al.^{4,8}

Figure 1 300 MHz 1H NMR spectra of ≈ 2 mM CTD and CTD–catecholate complexes obtained in D_2O at pH 7.5 (uncorrected) at 30 °C. (Reproduced by permission of the American Chemical Society from L. Que, Jr., R. B. Lauffer, J. B. Lynch, B. P. Murch, and J. W. Pyrz, *J. Am. Chem. Soc.*, 1987, **109**, 5381)

distance less than 6 Å could not be observed for any of the CTD complexes, due to shortening of T_2 and concomitant broadening of the resonances. For example, all aromatic ring protons of both exogenous and endogenous ligands were unobservable. Thus, the isotropically shifted resonances in both the native CTD and CTD–catechol spectra (Figure 1) must be due exclusively to endogenous ligand protons which are ≥ 6 Å away from the iron. This distance restriction, plus comparisons with the shifts of the synthetic complexes in Table 1, results in assignments of the two higher-frequency resonances (i.e., those between 50 and 80 ppm) in the CTD and CTD–catechol spectra to $C_\beta H_2$ protons of tyrosine ligands and the two or three lower-frequency resonances to $C_\beta H_2$ protons of N_ϵ -coordinated histidine. Due to the dependence of these shifts on the torsion angle θ_H (defined in the Introduction), two distinct isotropically shifted resonances are expected for each

$C_\beta H_2$ group. These two resonances will not be resolved if the two torsion angles for the constituent C–H bonds are similar to each other. Alternatively, two dissimilar torsion angles could result in one resonance of each pair being obscured by protein resonances between 0 and 10 ppm. Since other spectroscopic evidence indicated the presence of two different tyrosine ligands, the two higher-frequency resonances were assigned to two different tyrosyl $C_\beta H_2$ groups. Similarly, the observation of three isotropically shifted histidine $C_\beta H_2$ resonances suggests at least two histidine ligands. An X-ray crystal structure of another catechol dioxygenase has since confirmed the presence of two tyrosine and two histidine ligands.⁹ For reasons discussed in the Introduction, the relatively narrower linewidths for the CTD–catechol versus native CTD spectra were attributed to relatively higher values of the zero field splitting parameter, D , for the CTD–catechol iron sites. This conclusion is consistent with independent determinations of D values by Mössbauer spectroscopy.

The 6 Å observability restriction also applies to the coordinated catechol substrates of CTD. Thus, only those ring methyl protons in positions either *meta* or *para* to coordinated oxygen in CTD–methylcatecholate or –methylphenolate complexes are observable by NMR. The isotropic shifts observed for a series of Fe(III)(salen)–catecholate and –phenolate complexes [salen = 1,2-bis(salicylideneamino)ethane²⁻] show that the unpaired spin on Fe(III) is delocalized through the π system of the coordinated catecholate or phenolate, which results in alternating signs of the spins at the ring carbon π orbitals.^{4,8} This alternation in sign allows differentiation of the three possible coordination modes of 4-methylcatecholate to the iron center in CTD, namely, unidentate with either O-1 or O-2 coordinated or bidentate (O-1 and O-2 both coordinated). These three coordination modes are illustrated in Scheme 2 along with the observed 4-methyl ¹H NMR chemical shifts for the corresponding Fe(III)(salen)–4-methylcatecholate complexes.⁸

The 4-methyl chemical shift for the bidentate coordination mode is roughly the weighted average of the 4-methyl shifts for spin delocalization through both the O-1 and O-2 unidentate pathways. The 4-methyl resonance of the CTD–4-methylcatechol complex at 105 ppm (Table 2 and Figure 1, confirmed by CD₃ substitution) with no low-frequency resonance shows that 4-methylcatechol coordinates to the CTD iron center exclusively in the unidentate O-1 mode. Examination by NMR of a larger set of methyl-substituted phenols and catechols complexed to CTD confirms this interpretation. The unidentate coordination mode is believed to activate the catechol to oxidative cleavage relative to the bidentate coordination mode. Thus, these NMR studies provided a key insight into the catechol dioxygenase catalytic mechanism. These results also constitute a particularly elegant demonstration of how comparison with NMR data on synthetic complexes can be used to provide these insights.

Scheme 2

4 PURPLE ACID PHOSPHATASES

These eukaryotic enzymes catalyze the hydrolysis of phosphate esters and have molecular weights of about 40 000 Da. The active site contains a pair of metal ions, with one or both of the metals being iron. Two proteins in this class have been characterized by ¹H NMR: uteroferrin (Uf), isolated from the uterine fluid of pregnant pigs, and a purple acid phosphatase isolated from beef spleen (BS-PAP).^{3,10,11} In both of these enzymes the purple color has been established to be due to a tyrosine phenoxo → Fe(III) ligand-to-metal charge-transfer transition in an [Fe(II),Fe(III)] site. These mixed-valent forms (Uf_r and BS-PAP_r) are much more enzymatically active than the diiron(III) forms. The diiron(II) form is inactive and loses iron too rapidly to be useful for NMR.

The mixed-valent but not the diiron(III) oxidation levels have shown paramagnetically shifted ¹H NMR spectra up to now. This contrasting observability between the two oxidation levels is most likely due to the shorter τ_s of the mixed-valent cluster due its 50% Fe(II) character. Chemical shifts and assignments are listed in Table 3 for isotropically shifted ¹H NMR resonances of Uf_r and BS-PAP_r, and representative spectra are shown in Figure 2.^{3,10}

For the diiron sites in Uf and BS-PAP, antiferromagnetic coupling lowers the averaged electron spin moment at each iron below that for mononuclear complexes (cf. Introduction). For Uf_r, antiferromagnetic coupling between the $S_1 = \frac{5}{2}$ Fe(III) and the $S_2 = 2$ Fe(II) results in a ladder of half-integer spin states from $S_{\text{Tot}} = \frac{1}{2}$ at lowest energy to $\frac{9}{2}$ at highest energy. The temperature dependence of the Uf_r resonances listed in Table 3 when fitted to the modified Van Vleck equation referred to in the Introduction led to $-J = 10 \text{ cm}^{-1}$,¹¹ consistent with weak antiferromagnetic coupling. This value of J is essentially identical to that subsequently obtained from direct measurements of magnetic susceptibilities versus temperature for Uf_r.¹² Using this value, the resulting population of states in the spin manifold at 30 °C (the temperature of the NMR experiment) is calculated to result in a molar susceptibility of the cluster and, therefore, ligand contact shifts which are approximately 17% lower than those

Table 3 Chemical Shifts (ppm) of Isotropically Shifted ¹H NMR Resonances for Uf_r and BS-PAP_r at 30 °C^a

of mononuclear complexes. Therefore, the isotropic shifts in Table 3 must be increased by 17% in order meaningfully to compare these shifts with those in Table 1.

Previous Raman resonance evidence had indicated only one tyrosine ligand per Fe(III). The assignments of the C_βH_2 resonances of this coordinated tyrosine illustrate both the difficulties involved in assigning resonances and the evidence which was accumulated for these assignments. One difficulty was mentioned above for CTD, namely the dependence of the C_βH_2 shifts on the torsion angle according to $110f(\theta_\text{H})$ (cf. Table 1). Additional evidence was provided by T_1 measurements, which were used to estimate through-space Fe–H distances. Only resonance **a** in Figure 3 had a T_1 value (20 ms) appropriate for the Fe–H distance (≥ 6.7 Å) expected for a tyrosine ligand C_βH_2 proton. All other resonances had significantly shorter T_1 values and, therefore, must be due to protons closer to one or both irons. As can be seen from Figure 3, saturation of resonance **a** in Uf_r resulted in the largest NOE at resonance **j**. Thus, resonances **a** and **j** were assigned to the tyrosine ligand C_βH_2 protons of Uf_r. The large difference in chemical shift for resonances **a** and **j** indicates significantly different torsion angles for the two C_βH_2 protons. Based on these shifts, the torsion angles, θ_H as defined in equation (3), of the two C_βH_2 –H bond vectors with respect to the tyrosine phenyl ring normal were calculated to be 78° and 42°. Resonance **j** is difficult to observe except in the NOE difference spectrum, because it lies close to the diamagnetic envelope; in fact, resonance **j** is not observed in BS-PAP_r. The differences in chemical shifts of the **a,j** resonance pair between Uf_r and BS-PAP_r (cf. Table 3) are not due to differing amounts of spin delocalization onto the tyrosine rings in the two proteins, since the tyrosine C_γH protons (resonances **c** and **d** in Table 3 and Figure 2) have very similar chemical shifts in the two proteins. Rather the differences in the **a,j** resonance pair indicate different sets of torsion angles for the tyrosine ligand C_βH_2 protons in the two proteins.

Figure 3 NOE difference spectra of Uf_r in D_2O buffer at 300 MHz and 30 °C. Arrows indicate resonance irradiated. (Reproduced by permission of the American Chemical Society from Z. Wang, L.-J. Ming, L. Que, Jr., J. B. Vincent, M. W. Crowder, and B. A. Averill, *Biochemistry*, 1992, **31**, 5263)

Assignments of the remaining resonances in Table 3 were based on similar lines of evidence. The disappearance of resonances **b** and **e** in D_2O identifies them as belonging to His ligand NH protons. A proposed schematic structure of the Uf_r and BS-PAP_r diiron sites with hydrogens labeled according to their resonance assignments is shown in Figure 4. [The hydroxo bridge proton in the PAP_r diiron site is thought to be too close to the iron atoms to be observable by NMR. Similarly, the N_δ -coordinated His residue has C_βH_2 protons (not explicitly indicated in Figure 4) which are thought to be too close to the Fe(II) to be observable.] Thus, these NMR studies of purple acid phosphatases illustrate the attempt to attain an internally consistent set of resonance assignments based on the cumulative results.

Table 3 and Figure 4 also show that the assignments are not yet complete. The suggested assignment of the low-frequency resonance **y** to the tyrosine ligand $\text{C}_\epsilon\text{H}$ (cf. Figure 4) is consistent with the expected alternation in sign of the unpaired spin delocalized through the π system of the aromatic ring. This assignment is also consistent with the proximity of this proton to Fe(III), and hence its unobservability in BS-PAP_r spectra. Similarly, the relative proximity of the carboxymethylene protons shown in Figure 4 to the diiron site shortens both their T_1 and T_2 values, which makes the observation of their resonances in the NMR and NOE spectra discussed above difficult. A more recent approach to the observation and assignment of the carboxylate ligand resonances was based on replacement of Fe(II) in the diiron cluster of Uf_r with Co(II).¹³ The [Fe(III), Co(II)]Uf

Figure 4 Schematic structure of the diiron site in Uf and BS-PAP with proposed NMR assignments. (Reproduced by permission of the American Chemical Society from Z. Wang, L.-J. Ming, L. Que, Jr., J. B. Vincent, M. W. Crowder, and B. A. Averill, *Biochemistry*, 1992, **31**, 5263)

retained 50% of the native enzyme activity, and replacement of Fe(II) with Co(II) shortened τ_s of the cluster, thereby lengthening the ligand proton T_1 values sufficiently for their observation in both 1D NOE and 2D NOESY spectra (see *Cobalt(II)- and Nickel(II)-Substituted Proteins*). The NOESY spectrum of the [Fe(III),Co(II)]Uf showed clear connectivities of resonances at 64, 28.5, and 17.7 ppm, consistent with a YCH_2CH system where Y coordinates to the Co(II). Based on M–H distance estimates, it was concluded that only a carboxylate ligand could show the observed combination of proton T_1 values and NOE connectivities. These results provided the first direct evidence for a coordinated carboxylate in the purple acid phosphatases, and showed that NOESY spectra of paramagnetic nonheme iron sites in proteins are obtainable when proton T_1 values are greater than 10 ms.

5 HEMERYTHRIN

Hemerythrin (Hr), the oxygen carrier in certain marine invertebrates, also contains a diiron site whose structure is shown schematically in Scheme 3 for the [Fe(III),Fe(III)](met) oxidation level.¹⁴

N_ϵ from five histidine (His) residues provide terminal ligands, and carboxylates from glutamate (Glu) and aspartate (Asp) provide two bridging ligands. A bridging oxo ligand is provided by the solvent. The protein ligands do not change upon reduction to the [Fe(II),Fe(II)](deoxy) oxidation level, but the oxo bridge is converted to a hydroxo bridge. The diiron

Scheme 3

Scheme 4

site in Hr is, thus, richer in histidine ligands and poorer in oxygen ligands than that in Uf or BS-PAP.

The diiron site in Hr has probably been structurally, electronically, and chemically characterized in more detail than any other diiron protein. Nevertheless, 1H NMR was able to clarify or confirm certain aspects of the diiron site structure and reactivity. Perhaps the most important aspect concerns the currently accepted oxygenation mechanism shown in Scheme 4.¹⁴

The oxyHr diiron site is best formulated as $[Fe(III)(\mu-O)Fe(III)O_2H^{-1}]$, i.e., like the met oxidation level, oxy formally contains an oxo-bridged diiron(III) site. The internal proton transfer which occurs upon interconversion of the deoxy and oxy forms has not been observed directly by any spectroscopic technique. However, 1H NMR isotropic shifts can provide indirect measurements of magnetic susceptibility and, due to the expected differences in antiferromagnetic coupling mediated by an oxo versus a hydroxo bridge, can thereby provide evidence for the nature of the bridging ligands in deoxy- and oxyHr. As discussed above for the purple acid phosphatases, antiferromagnetic coupling in the Hr diiron site reduces the magnetic moments and, thereby, the ligand contact shifts below the values for mononuclear complexes. Antiferromagnetic coupling between the $S_1 = S_2 = \frac{5}{2}$ Fe(III) centers in oxy- and metHr or the $S_1 = S_2 = 2$ Fe(II) centers in deoxyHr leads to a ladder of integer spin states from $S_{Tot} = 0$ at lowest energy to $S_{Tot} = 5$ (met and oxy) or 4 (deoxy) at highest energy.¹⁴

Despite the relatively high molecular weight of Hr (an octamer of 108 000 Da), isotropically shifted resonances have been observed for deoxy-, oxy-, and metHrs.^{15,16} 1H NMR spectra of these three forms are shown in Figure 5, and Table 4 lists the chemical shifts of the isotropically shifted resonances for these three forms. As expected from the longer τ_s of Fe(III), the resonances are much narrower for deoxy-[Fe(II),Fe(II)] than for oxy- and metHrs [Fe(III),Fe(III)]. The His ligand $N_\delta H$ resonances were assigned based on their solvent exchangeability (cf. Scheme 2).

The $N_\delta H$ chemical shifts for deoxyHr are only slightly smaller than observed for mononuclear Fe(II) complexes (Table 1), indicating only a small antiferromagnetic interaction assuming that the isotropic shifts are predominantly contact in nature. Dipolar contributions are probably at least partially responsible for the relatively wide range of His ligand $N_\delta H$ chemical shifts (40–65 ppm). Nevertheless, the temperature

Table 4 Chemical Shifts of Paramagnetically Shifted ^1H NMR Resonances for Various Forms of Hemerythrin^a

^aFrom Maroney et al.¹⁶

dependence of the deoxyHr N_δH shifts between 30°C and 60°C , when fitted to the modified Van Vleck equation referred to in the Introduction, led to values of $-J$ in the range of $10\text{--}20\text{ cm}^{-1}$, i.e., consistent with weak antiferromagnetic coupling. This range for $-J$ is in good agreement with that determined by an Evans's NMR susceptibility study (-15 cm^{-1}),¹⁶ and with that subsequently determined for deoxyHr by magnetic circular dichroism spectroscopy ($12\text{--}38\text{ cm}^{-1}$).¹⁷ The range of $-J$ values determined for deoxyHr encompasses the value of -13 cm^{-1} reported for a synthetic $(\mu\text{-hydroxo})\text{bis}(\mu\text{-carboxylato})\text{diiron(II)}$ complex, and is thus consistent with the deoxyHr diiron site structure shown in Scheme 4. The resonances at 11 and 14 ppm for deoxyHr can be tentatively assigned to His ligand C_βH_2 protons (cf. Table 1), especially if these shifts have some downfield dipolar contributions. The resonances to low frequency of zero listed in Table 3 are solvent nonexchangeable but their assignments remain a mystery; the low-frequency shifts are presumably due to dipolar contributions.

The His ligand N_δH chemical shifts for oxy- and metHr (13–24 ppm) are much smaller than for mononuclear Fe(III) sites (Table 1), reflecting the relatively strong antiferromagnetic coupling in these forms. This strong coupling makes the temperature dependence of the isotropic shifts too flat for a reliable determination of J . However, the His ligand N_δH chemical shifts for both oxy- and metHr are very similar to the terminal imidazolyl ligand NH chemical shifts (15 and 19 ppm) reported for a synthetic $(\mu\text{-oxo})\text{bis}(\mu\text{-acetato})\text{diiron(III)}$ complex with $-J = 120\text{ cm}^{-1}$.⁷ The analogous $(\mu\text{-hydroxo})\text{bis}(\mu\text{-acetato})\text{diiron(III)}$ complex has the imidazolyl NH chemical shifts to much higher frequency ($\geq 85\text{ ppm}$), as expected from its much lower value of $-J$ ($\approx 17\text{ cm}^{-1}$).¹⁸ A similar observation can be made for the nonexchangeable resonance at 11 ppm for oxy- and metHr. This feature is assigned to one or more of the four C_βH_2 and $\text{C}_\gamma\text{H}_2$ protons of the bridging Asp and Glu carboxylate ligands (cf. Scheme 3). The aforementioned synthetic $(\mu\text{-oxo})$ - and $(\mu\text{-hydroxo})\text{bis}(\mu\text{-acetato})\text{diiron(III)}$ complexes exhibit acetate methyl resonances at 10 and 66 ppm, respectively.⁷ Thus, the putative bridging carboxymethylene resonance at 11 ppm together with the His ligand N_δH resonances between 24 and 13 ppm support an oxo- rather than hydroxo-bridged structure in oxyHr, i.e., the hydrogen-bonded proton is associated more strongly with the peroxo ligand than the oxo bridge, as shown in Scheme 4. These isotropic shifts are also qualitatively consistent with values of $-J = 77$ and 134 cm^{-1} obtained for oxy- and metHr, respectively, in an earlier magnetic susceptibility study.¹⁸ However, the similarity in the isotropic shifts of the oxy and met forms suggests that the difference in J between these two forms is less than

57 cm^{-1} . [The contact shifts of the bridging carboxymethylene protons are expected to depend on their torsion angles, θ_{H} , according to equation (3). Thus, given the acetate methyl resonance at 10 ppm for the synthetic oxo-bridged diiron(III) complex and a diamagnetic shift of 2 ppm for acetate, the bridging carboxymethylene proton isotropic shifts for an oxo-bridged diiron(III) site with $-J = 120\text{ cm}^{-1}$ should be $\approx 8(2\cos^2\theta_{\text{H}})$ or $\approx 0\text{--}16\text{ ppm}$. The 11 ppm resonance for oxy- and metHr falls within this range (even after subtraction of a diamagnetic shift). A similar analysis indicates that an 11 ppm resonance is too far downfield to be assigned to C_βH_2 of N_ϵ -coordinated His ligands in a strongly antiferromagnetically coupled diiron(III) site.]

The Hr diiron site can also be prepared in a mixed-valent form, so-called 'semi-met' Hr. As for Uf_r , antiferromagnetic coupling leads to an $S_{\text{Tot}} = \frac{1}{2}$ ground state with a characteristic EPR spectrum. This mixed-valent diiron site is expected to have a shorter τ_s than does the diiron(III) site and therefore narrower isotropically shifted resonances, an expectation which is borne out by the spectra. The azide adduct of semi-metHr is particularly stable and was examined in some detail by NMR. Two solvent-exchangeable paramagnetically shifted resonances were observed for semi-metHrN₃ at 72 and 54 ppm (40°C) with a respective intensity ratio of approximately 2:3 (cf. Figure 5). Based on the 2:3 ratio of His ligands to Fe-2:Fe-1 shown in Scheme 3, the 72 ppm resonance was assigned to the N_δH of the two His ligands to Fe-2. Due to the larger paramagnetic shift, Fe-2 is assumed to be in the Fe(III) ($S = \frac{5}{2}$) state in semi-metHrN₃. Similarly, the 54 ppm resonance is assigned to the three His ligand N_δH s of Fe-1, which must then be in the Fe(II) ($S = 2$) state. Here again, due to antiferromagnetic coupling, the chemical shifts are smaller than those for mononuclear complexes (cf. Table 1). Possible dipolar contributions complicate a more quantitative analysis of the Fe(II) ligand resonance. On the other hand, the 72 ppm resonance assigned to the Fe(III) center should not have significant dipolar contributions and should, therefore, be proportional to the magnetic susceptibility of the Fe(III) center in the diiron cluster. Assuming an 8 ppm diamagnetic shift for histidine N_δH , the isotropic shift assigned to the Fe(III) center in semi-metHrN₃, $72 - 8 = 64\text{ ppm}$, relative to the isotropic shift expected for mononuclear Fe(III), $\approx 102 - 8 = 94\text{ ppm}$, translates to an approximate 32% reduction in susceptibility of the Fe(III) center in semi-metHrN₃ relative to that expected for mononuclear Fe(III). Using the modified Van Vleck equation, this reduction in susceptibility corresponds to a calculated $-J = 18\text{ cm}^{-1}$.¹⁶ Analysis of the temperature dependence of the 72 ppm resonance between 30°C and 60°C using the same equation led to a very similar value of $-J$. More recent magnetic circular dichroism studies yield

Figure 5 300 MHz ^1H NMR spectra in the high-frequency region of (from top to bottom) met- and oxyHr at 30°C , and deoxyHr and semi-metHrN₃ at 40°C . Note the differing ppm scales of the spectra. Kurtz, Jr., J. M. Nocek, L. L. Pearce, and L. Que, Jr., *J. Am. Chem. Soc.*, 1986, **108**, 6871)

$-J \approx 8\text{ cm}^{-1}$ for the semi-met oxidation level of Hr.¹⁷ This lower value may be due to inclusion of zero field splitting of the Fe(II) center, which was not taken into account in the NMR analyses. In any case, $-J$ values of $8\text{--}20\text{ cm}^{-1}$ are thought

to be too small for an oxo bridge and rather favor a hydroxo bridge between the Fe(II) and Fe(III) in the diiron site of semi-metHr. No resonances could be definitively assigned to the bridging carboxymethylene protons in semi-metHr.

Myohemerythrin is an O_2 -carrying protein with a diiron site nearly identical to that in Hr, but myoHr is a monomer with a molecular weight $\approx 13\,700\text{ Da}$, i.e., one-eighth that of the octameric Hr. Despite the expected narrowing of resonances due to an increased rotational correlation time, no reports of ^1H NMR spectra of myoHr have yet appeared.

6 RIBONUCLEOTIDE REDUCTASE

Ribonucleotide reductases (RNRs) catalyze the reduction of ribonucleotides to 2'-deoxyribonucleotides, which represents the first committed step in DNA synthesis. The RNR which functions during aerobic metabolism in *E. coli* contains a diiron site in each subunit of a dimer called protein R2 ($M_r \approx 87\,500$).¹⁴ The diiron site does not interact directly with the substrate, but instead generates a stable tyrosyl radical which is essential for substrate turnover. A metastable, highly-oxidizing diiron species resulting from reaction of the diiron(II) site in reduced R2 protein with O_2 abstracts a hydrogen atom from the hydroxy group of a proximal, nonligating tyrosyl residue, thereby creating the tyrosyl radical. An X-ray crystal structure is available for the diiron(III) form of the RNR-R2 protein (metR2), and the diiron site structure in this form is shown schematically in Scheme 5.¹⁹

The radical forming tyrosyl residue (not shown in Scheme 5) is located approximately $5\text{ \AA}$ from Fe-1. The enzymatically active form of protein R2 is known to contain a diiron(III) site, presumably having the same structure as in metR2, but containing in addition the tyrosyl radical. As for Hr, the diiron site ligation in RNR-metR2 consists of a bridging oxo ligand from the solvent plus carboxylate and histidyl ligands from amino acid side chains. However, several distinct differences between the diiron sites in Hr and RNR are readily apparent. One rather than two carboxylate ligands bridges Fe-1 and Fe-2 in RNR-metR2. The terminal ligands consist of a mixture of carboxylates and histidyl imidazoles, with only two of the latter, one on each iron. In contrast to Hr, the His ligands in RNR are ligated through N $_{\delta}$ rather than N $_{\epsilon}$. An X-ray crystal structure of the diiron(II) site in reduced RNR-R2 is not yet available, but the X-ray crystal structure of a dimanganese(II)-substituted form shows two O,O' -bridging carboxylates from two Glu residues as the only bridging ligands.¹⁴ Isotropically shifted ^1H NMR resonances have been observed for both

RNR-metR2

active R2 and reduced R2.²⁰ The spectra of these two forms are reproduced in Figure 6. The mixed-valent form has so far proven too unstable to be examined by NMR.

The active R2 spectrum shows one solvent-exchangeable resonance at 24 ppm, assigned to $\text{N}_\epsilon\text{H}$ of the coordinated His residues, and one nonexchangeable resonance at 19 ppm [cf. Figure 6(b), (d) and (f)]. From comparisons with the spectra of met- and oxyHr and synthetic complexes discussed in Section 5, the chemical shift of the His ligand $\text{N}_\epsilon\text{H}$ resonance suggests a strongly antiferromagnetically coupled diiron(III) site in active R2. The temperature dependences of both the 19 and 24 ppm resonances are essentially flat between 20°C and 37°C , as expected for a diiron(III) site with $-J > 100\text{ cm}^{-1}$ and for the oxo-bridged structure shown in Scheme 5. The 19 ppm resonance has not yet been assigned. Given the strong antiferromagnetic coupling, 19 ppm is too large a shift for C_δH of an N_δ -coordinated His ligand and is at the outer edge of the range expected for bridging carboxymethylene protons. Terminal carboxymethylene protons remain a possible assignment for the 19 ppm resonance.

The reduced R2 was obtained by addition of $\text{Fe(II)}_{(\text{aq})}$ to apoR2, i.e., metal-free R2 whose spectrum is shown in Figure 6(e). The spectra of this reduced R2 are shown in Figure 6(a) and (c). Two isotropically shifted resonances are observed at 57 and 45 ppm, with the former being solvent-exchangeable and therefore assigned to the His ligand NH. Assuming the shift is predominantly contact in origin, an NH ligand resonance at 57 ppm falls within the range for mononuclear Fe(II) complexes (cf. Table 1) and indicates little or no magnetic coupling between the two Fe(II) centers of the reduced diiron site. This conclusion is supported by the temperature dependences of the isotropic shifts, which suggest $-J = 5 \pm 5\text{ cm}^{-1}$. Comparisons with synthetic complexes indicate that a $-J$ value near zero is consistent with a bis(μ -carboxylato)diiron(II) core with no other bridging ligands,

Scheme 6

as inferred from the structure of the Mn(II) -substituted R2 protein. The 45 ppm resonance has not been assigned; C_δH of N_δ -coordinated His residues and $\text{C}_\gamma\text{H}_2$ of bridging Glu ligands are both consistent with the observed shift. Thus, although relatively limited compared with other diiron proteins, the available information on paramagnetically shifted ^1H NMR resonances of RNR-R2 fully support the diiron site structures in this enzyme which were determined by other means.

6.1 Isopenicillin N-Synthase

Isopenicillin N-synthase (IPNS) is found in some microorganisms and catalyzes the oxidative ring closure shown in Scheme 6, resulting in conversion of the substrate δ -(L - α -aminoadipoyl)- L -cysteiny-D-valine (ACV) to isopenicillin N.

Oxygen is also a substrate for IPNS but is reduced completely to H_2O rather than incorporated into ACV. IPNS from *Cephalosporium acremonium* has a molecular weight of 38 400 Da and contains a mononuclear nonheme Fe(II) active site, which has been examined by ^1H NMR.⁶ No Fe(III) form of IPNS has been reported. In the absence of O_2 , the substrate ACV binds to the Fe(II) active site without transformation into product; therefore, ^1H NMR spectra of IPNS can be compared with that of the IPNS-ACV complex. Nitric oxide (NO) also binds to IPNS and to the IPNS-ACV complex, forming binary and ternary complexes, respectively, which are assumed to be analogous to the transient complexes formed with O_2 . However, unlike those with O_2 , the IPNS-NO complex and the IPNS-ACV-NO complex are sufficiently stable to allow examination by NMR. ^1H NMR spectra of these various IPNS complexes are shown in Figure 7. The intensities of the peaks were integrated against that of an external standard.

The Fe(II) IPNS spectrum [Figure 7(a)] shows a cluster of overlapping, solvent-exchangeable features centered near 65 ppm, which integrates to three protons. This shift falls in the range of N_δH or $\text{N}_\epsilon\text{H}$ for His residues coordinated to Fe(II) (cf. Table 1) and the 65 ppm feature is therefore assigned to three His ligands. The solvent nonexchangeable resonance at 42 ppm with an intensity of two protons is within the range for a coordinated Asp C_βH_2 or Glu $\text{C}_\gamma\text{H}_2$ (cf. Table 1) whose constituent protons have sufficiently similar torsion angles that their resonances are not resolved. Further NMR evidence for a carboxylate ligand was obtained on an inactive form of IPNS in which Co(II) is substituted for Fe(II) . The shorter τ_s of Co(II) facilitated NOE studies on the

Figure 7 300-MHz ^1H NMR spectra of IPNS at 10°C of (a) Fe(II)IPNS, (b) Fe(II)IPNS-NO complex, (c) Fe(II)IPNS-ACV complex under argon, and (d) Fe(II)IPNS-ACV-NO ternary complex under argon. All samples at pH 7 in H_2O . Starred peaks disappear in D_2O . (Reproduced by permission of the American Chemical Society from L.-J. Ming, L. Que, Jr., A. Kriauciunas, C. A. Frolik, and V. J. Chen, *Biochemistry*, 1991, **30**, 11 653)

isotropically shifted resonances, which showed clear evidence for a $\text{YCH}_2\text{CH}<$ spin system where Y coordinates to Co(II).⁶ This result favors the assignment of the 42 ppm resonance of Fe(II)IPNS to a coordinated Asp C_βH_2 or Glu $\text{C}_\gamma\text{H}_2$ over a possible alternative assignment to C_δH of two N_δ -coordinated His residues. Although irradiation of the 42 ppm resonance of Fe(II)IPNS did not reveal any NOE connectivities, this negative result is presumably due to the shorter T_1 values for Fe(II)IPNS than for Co(II)IPNS.

The solvent-exchangeable resonance near 24 ppm seen in all of the spectra in Figure 7 has no obvious assignment; it is well out of the range for the His ligand NH which is the only solvent-exchangeable proton listed in Table 1. Protons from water or hydroxide ligands to Fe(II) should resonate much farther to high frequency²¹ and would be extremely broad due to their proximity to Fe(II). The 24 ppm solvent-exchangeable resonance could be due an uncommon protein ligand, such as *O*-coordinated amide or to a nonligand proton which is hydrogen bonded to the Asp ligand.

The substrate ACV (cf. Scheme 6) is known from other evidence to coordinate to Fe(II) through the sulfhydryl sulfur.

Upon binding of ACV, the 65 ppm feature in Figure 7(a) splits into two resonances with a 2:1 intensity ratio [cf. Figure 7(c)]. These two resonances are assigned to the three His ligand NHs with the lower frequency, less intense resonance assigned to a His ligand whose Fe-N bond strength has been weakened by coordination of ACV. The 42 ppm resonance also splits into two features, and the mysterious solvent-exchangeable feature near 24 ppm is preserved. Thus, all of the protein ligands apparently remain coordinated upon ACV binding. Curiously, no paramagnetically shifted resonances were assigned to coordinated ACV. According to the data in Table 1, a resonance analogous to the C_βH_2 of coordinated cysteine near 200 ppm might be expected for sulfur-coordinated ACV. The Co(II)IPNS spectrum shows a resonance at 86 ppm, which was assigned to the Cys C_βH_2 -like protons of sulfur-coordinated ACV. The shorter τ_s of Co(II) apparently favors observation of these proximal protons.

The Fe(II)IPNS-NO complex shows one solvent-exchangeable feature near 67 ppm [cf. Figure 7(b)] which integrates for three protons and is therefore logically assigned to the three His ligands whose resonances are observed at ≈ 65 ppm in the absence of NO [cf. Figure 7(a)]. The similarity in NH resonance positions and linewidths means that NO binding has not greatly perturbed either the spin delocalization onto the ligands or τ_s of the Fe(II), despite a change in spin state from $S = 2$ for high-spin Fe(II) to $S = \frac{3}{2}$ for [Fe(II)NO]. However, the solvent-nonexchangeable 42 ppm two-proton resonance seen in the Fe(II)IPNS spectrum [Figure 7(a)] has disappeared upon binding of NO. If, as discussed above, the 42 ppm resonance is due to the carboxymethylene protons of a coordinated Asp or Glu residue, then one explanation for the disappearance of this resonance is dissociation of the carboxylate ligand upon NO binding. However, one expects that neutral His ligands or water would be more readily displaced than a negatively charged carboxylate ligand. If the 42 ppm resonance is alternatively assigned to C_δH of N_δ -coordinated His residues, then disappearance of this resonance due to dissociation of two His ligands should be accompanied by a decrease in intensity of the 65 ppm feature in Figure 7(a) assigned to the three His ligand NH's. However, this line of reasoning is inconsistent with the three-proton intensity of the 67 ppm feature in Figure 7(b). Therefore, the explanation favored by the authors for disappearance of the 42 ppm resonance upon NO binding is severe alteration but not displacement of a carboxylate ligand. One possible type of 'severe' alteration is conversion of carboxylate coordination from the *syn* to the *anti* lone pair, which, as discussed in Section 3, would tend to weaken the Fe-O(carboxylate) bond, and could thereby shift the ligand carboxymethylene resonance to a position under the diamagnetic proton envelope. This change in carboxylate coordination is illustrated in Figure 8.

The Fe(II)IPNS-ACV-NO complex [Figure 7(d)] also lacks the 42 ppm resonance and shows two solvent-exchangeable resonances of equal intensity at 62 and 74 ppm, which together integrate to two rather than three protons. This result is interpreted to mean that one of the His ligands has dissociated upon formation of the ternary complex. Figure 8 shows the proposed model for the structural changes in the IPNS active site upon binding of ACV and NO, which is consistent with the NMR and other spectroscopic results.

7 SUMMARY AND FUTURE DIRECTIONS

^1H NMR of paramagnetic nonheme iron proteins has proven to be quite useful for the identification of ligand type and coordination geometry when used in conjunction with other spectroscopic data and chemical information, at least for proteins of $M_r \leq 100\,000$ Da. One of the most important contributions of ^1H NMR has been in elucidation of the magnetic behavior of diiron clusters in nonheme proteins, which has assisted in assigning the bridging ligands. Definitive assignments of resonances have been hampered in some cases by the difficulty of conducting NOE and NOESY experiments on paramagnetic proteins containing nonheme, high-spin Fe(II) or Fe(III). However, as the technology improves and disperses, these methods are likely to be increasingly applied to nonheme iron proteins. As discussed for uteroferrin,¹³ preparation of mixed-metal sites [e.g., Fe(III), Co(II)] with shorter τ_s values and resulting longer ligand proton T_1 values offer a promising approach for NOE and NOESY studies (see *Cobalt(II)- and Nickel(II)-Substituted Proteins*). Also, as these proteins are increasingly cloned and overexpressed, isotopic labeling of residues may assist in assignments, especially of solvent nonexchangeable resonances (see *Enzymatic Transformations: Isotope Probes*). Studies of these types are likely to yield increasingly quantitative and definitive analyses of the isotopically shifted ^1H NMR resonances of nonheme iron proteins.

Several other nonheme iron proteins would seem to be prime candidates for ^1H NMR studies of their iron sites. These proteins include myohemomerythrin, iron superoxide dismutases,²² lipoygenases,²³ nitrile hydratases,²⁴ iron-activated alcohol dehydrogenases,²⁵ stearoyl CoA Δ^9 -desaturase,²⁶ and rubrerythrin.²⁷ (In fact, one- and two-dimensional ^1H NMR studies of iron superoxide dismutase have recently been reported.²⁸) Thus, there is unlikely to be a shortage of novel proteins to which the powerful methods described above can potentially be applied.

1 INTRODUCTION

Transferrins are a family of metal binding glycoproteins which play a fundamental role in iron metabolism in vertebrates and invertebrates.¹ Transferrin from serum (Tf hereafter) acts as the principal iron carrier in plasma, binding the Fe^{3+} ion strongly and reversibly and shuttling it from the sites of metal uptake to those of iron-proteins biosynthesis and iron storage. Ovotransferrin from avian egg white (Otf), and lactoferrin (Ltf) found in many secretory fluids and in leukocytes, are mainly iron-sequestering proteins which exert a bacteriostatic and detoxifying function. Transferrins are monomeric proteins of about 700 residues with molecular weight close to 80 kDa. They are related by a sequence homology of about 50%. The X-ray structural information^{2,3} indicates that the polypeptide chain is organized into two nearly equal-sized and about 40% homologous globular lobes connected by a short peptide segment, each containing one chain terminus (hence termed N-lobe and C-lobe), and one metal site (Figure 1). Each lobe is in turn structured into two domains. The metal lies at the bottom of the cleft between the two domains, about 10 Å from the protein surface. Both metals are bound by two tyrosines, one histidine, and one aspartate in a pseudooctahedral coordination which is completed by a bidentate carbonate ion hydrogen bonded to some protein groups (Figure 1).^{2,3} X-ray data also indicate the absence of metal-coordinated water in the crystal.

The requirement of a concomitant (synergistic) binding of an anion (besides carbonate, carboxylate anions with a second donor group are also active) for specifically loading the metal in the two sites is a unique feature of the biochemistry of transferrins. In recent years X-ray crystallography and NMR have allowed the elucidation of several molecular details of the metal sites. It is apparent that the formation of the ternary complex at both sites proceeds through initial anion binding to the protein: the anion is most probably required to reduce the net positive charge in the binding cavity, due to the presence of a number of cationic residues, and for increasing the overall stability of the adduct by further anchoring the metal to the protein. Overall, it functions as a bridge between the metal and the protein. The synergistic anion appears to play a central role in the reactivity of the metal centers, acting as the key for the processes of metal uptake and release. The associated protein conformational changes are also being extensively studied, in

Figure 1 (a) $\text{C}\alpha$ plot of the lactoferrin molecule showing its subdivision into two lobes, the N-lobe (top) and C-lobe (bottom). The iron atoms are shown as filled circles bound in the cleft between the two domains in each lobe. (b) The metal- and anion-binding site in lactoferrin (N-lobe). The carbonate anion is shown by hatched circles. Hydrogen bonds are indicated by dotted lines. (Reproduced by permission of Academic Press from B. F. Anderson, H. M. Baker, G. E. Norris, D. W. Rice, and E. N. Baker, *J. Mol. Biol.*, 1989, **209**, 711)

particular the open–close equilibrium of the interdomain cleft at each lobe, with metal binding and removal occurring only in the open form.

The two metal sites of transferrins are, in general, spectroscopically slightly inequivalent and differ, although most often not dramatically, in metal binding affinity. The relative binding strength of the two sites is sensitive to pH, synergistic anion, and ionic composition of the medium, and may vary toward different metals. However, the C-site almost invariably shows a greater metal affinity than the N-site at acidic pH. The structural bases of these differences are still not unequivocally

established (although the disulfide bridge content of the two lobes appears to be relevant in this respect). Their physiological relevance is also under investigation. The biological requirement for the structural 'doubleness' of transferrins is nowadays a central issue.

Transferrins can firmly bind a large number of transition, nontransition, and lanthanide ions. Several metals have served as spectroscopic probes for investigating the structural features of the metal sites, but some of the adducts also have a biological relevance since serum transferrin, being only about 30% saturated with iron in vivo, may function as an efficient carrier for metals other than iron.

2 THE ROLE OF NMR IN THE CHEMISTRY OF TRANSFERRINS: ACHIEVEMENTS

It should be recalled that for a protein of the size of transferrin full structural studies in solution (see *Biological Macromolecules: Structure Determination in Solution; Biological Macromolecules; Biological Macromolecules: NMR Parameters; Multidimensional Spectroscopy: Concepts; Structures of Larger Proteins, Protein-Ligand, and Protein-DNA Complexes by Multi-Dimensional Heteronuclear NMR*) are not yet feasible. The NMR of transferrins was until recently mainly devoted to the elucidation of the molecular details of the ternary adducts at the metal sites with the following methodological approaches: (a) ^{13}C NMR of protein derivatives of diamagnetic metals with ^{13}C -enriched anions; (b) observation of protein-bound NMR active metal nuclei; (c) observation of ^1H NMR hyperfine-shifted resonances arising from the protons surrounding a bound paramagnetic metal (see *Electron-Nuclear Hyperfine Interactions; Cobalt(II)- and Nickel(II)-Substituted Proteins; Electron-Nuclear Multiple Resonance Spectroscopy*); (d) NMRD profiles. Only in recent years, has one- and two-dimensional ^1H NMR at high field (see *Multidimensional Spectroscopy: Concepts*) succeeded in handling, at least partially, the largely unresolved proton spectrum and proved to be of use in monitoring metal binding to the protein and the related conformational changes. In what follows we have outlined the contribution of NMR to the understanding of the main issues of the metallobiochemistry of transferrins.

2.1 Identification of the Metal-Binding Residues

The involvement of tyrosine residues in metal binding at both sites of transferrins, indicated by a number of spectroscopic and chemical modification studies, has been conclusively supported by ^1H NMR since the early 1970s from the shift induced in the corresponding resonances by Ga^{3+} binding, and their paramagnetic broadening upon Fe^{3+} binding (see *Paramagnetic Relaxation in Solution*).⁴ In addition, two histidines were also proposed as metal ligands from the detection of the C(2)H resonances which did not titrate with pH in the Ga^{3+} ternary complexes⁵ of either intact or half molecules of Otf and human Tf.^{6,7} (Ga^{3+} has proved to be a good diamagnetic substitute for the Fe^{3+} ion, owing to the similarity of the ionic radius and to a similar binding affinity for transferrins). Metal binding of two histidines and two tyrosines was also consistent with the hyperfine shifted ^1H

resonances in the mono- and bis- Co^{2+} derivatives of Otf.^{8,9} The spread of the hyperfine shifted signals and their relatively long relaxation times¹⁰ (see *Paramagnetic Relaxation in Solution and Cobalt(II)- and Nickel(II)-Substituted Proteins*) suggested octahedral coordination around the metal ions.^{8,9}

The X-ray structure later confirmed octahedral coordination and the presence of two tyrosine ligands, but showed that only one of histidine is involved in the metal binding site.^{2,3} The identity of the additional nontitrating histidine in the Ga^{3+} derivative remains unknown, while the additional hyperfine shifted exchangeable proton in the spectrum of the Co^{2+} derivative could well arise, in retrospect, from one of the NH protons H bonded to the metal-coordinated carbonate ion.

Cadmium-113 NMR¹¹ (see *Cadmium-113 NMR: A Surrogate Probe for Zinc and Calcium in Proteins*) and ^{205}Tl NMR data¹² (see *Thallium NMR*) are in full agreement with the presence of only one histidine in the binding set. Aspartate coordination invariably went undetected, most probably due to the rather elusive ^1H NMR spectral changes in the crowded aliphatic region upon metal binding and the impossibility of metal NMR to discriminate it from other potential oxygen donors.

2.2 Exchangeable Protons in the Metal Sites

The issue of possible water coordination was tackled through water proton relaxation measurements. Early studies of water T_1 measurements in solutions of the Fe^{3+} adducts of Htf and Otf simply showed the accessibility of both sites to water molecules.^{13,14} This was substantiated later by measurements of the field dependence of the longitudinal nuclear magnetic relaxation rates of water protons (NMRD profiles) on the iron adduct of Htf, also carried out for comparative purposes on the apoprotein and the diamagnetic analog containing Co^{3+} , which were interpreted as indicative of a water molecule only loosely bound to the metal in each site.^{15,16} Analogously, one water molecule axially bound to the metal was also proposed for the Cu^{2+} derivative of Htf.¹⁷ It was later shown that for slowly rotating protein complexes the anisotropic structure of the ligand fields of the complexed metals is not averaged out as it is for fast rotating aqua ions or small complexes.^{18,19} The NMRD profiles for Cu^{2+} and VO^{2+} complexes of Htf were then evaluated with computations that included the anisotropic hyperfine interaction of metal ions with their own nuclei (see *Electron-Nuclear Hyperfine Interactions*).²⁰ It was found that relaxation occurs through exchange of bulk water with a second coordination sphere water molecule. This was also confirmed for the Gd^{3+} -Htf complex²¹ (see *Gadolinium Chelates: Chemistry, Safety and Behavior*) and demonstrated later by the X-ray structure of human Ltf.³ Recent²² more quantitative interpretation of the NMRD data for Fe^{3+} -Htf,²³ taking into account zero field splitting of the iron ion,^{18,19,24} suggests the presence of slowly exchanging protons (possibly from the protein) and of fast exchanging water at about 4–5 Å from the metal ion. NMRD data on Cu^{2+} -transferrin were also instrumental in demonstrating rotation-independent electronic relaxation mechanisms for Cu^{2+} in solution.²⁵

2.3 Synergistic Anions in the Metal Sites

Elucidation of the anion binding arrangement in the metal sites was obtained from a number of ^{13}C NMR data using

Table 1 ^{13}C NMR Chemical Shifts for ^{13}C -Enriched Synergistic Anions in Various Metal–Transferrin Derivatives^a

Derivative	Chemical shift ^b	
Carbonate derivatives		
Co ³⁺ – Htf ²⁷	169.5	169.3

^bIn ppm from Me_4Si .

^{13}C -enriched anions (mainly carbonate and oxalate) and/or NMR-active nuclei loaded in the protein sites. The spectral parameters and resonance assignments to individual sites, where available, have been collected in Table 1 and 2. The broadening beyond detection of the ^{13}C NMR resonance of isotopically-enriched bicarbonate bound to Fe^{3+} –Tf²⁶ allowed an estimate to be made of an upper limit of 9 Å for the Fe – ^{13}C distance, which was later reduced to 4.5 Å²⁷ thanks to instrumental developments, consistent with the presence of the anion in the first coordination sphere of the metal. The latter study also indicated that the anion, most probably carbonate rather than bicarbonate as judged by the ^{13}C chemical shift value, was specifically bound in both metal binding sites of the diamagnetic Co^{3+} derivative and of the apoenzyme, giving rise in both cases to resonances in slow exchange with that of free bicarbonate (see *Chemical Exchange Effects on Spectra*).²⁷ Specific anion binding to the apoprotein was taken as indicative that anion binding to the sites may precede metal binding, which is now indeed a widely accepted step in the mechanism of metal uptake of transferrins. A positively charged arginine residue was suggested as one of the anion

binding groups for carbonate,²⁷ as later confirmed by X-ray data. The pH dependence of the ^1H NMR resonances of the histidine C(2)H protons in diamagnetic $\text{Ga}(\text{III})$ derivatives of Otf, Htf, and their half-molecules in the presence of dicarboxylic acids as synergistic anions indicated a histidine as the likely anion binding group in each site.^{5–7,28} Interestingly, the X-ray structure of human Ltf allows for binding of anions larger than carbonate not to the arginine involved in the carbonate derivative, but to polar residues of a cavity beyond such a residue, which actually also includes a histidine residue.³

Further ^{13}C NMR studies of diamagnetic Al^{3+} –, Ga^{3+} – and Zn^{2+} –transferrin derivatives with carbonate and oxalate as the synergistic anion^{29,30} were interpreted in terms of the anion bridging the metal and a positively charged group of the protein, in line with the ‘interlocking-sites’ model (Figure 2).³¹ Oxalate bound in the Ga^{3+} – and Al^{3+} –Otf derivatives gave rise to two partially overlapped AB signal patterns.²⁹ The inequivalence of the two carbon atoms was assumed to arise from oxalate binding to the metal via only one carboxylate group, the other interacting with a positive residue of the site. Reference to ^{13}C chemical shift data of simple inorganic oxalate complexes allowed the assignment of the resonances of the protein-bound and metal-bound carbons of each oxalate molecule.^{29,30} In the case of Zn^{2+} –²⁹ and Cd^{2+} –Otf–oxalate derivatives,³² the effect of the metal on the shielding of the carbon atom is more similar to that of the protein residue, leading to the equivalence of the two carbon atoms (see *Magnetic Equivalence*), hence to the observation of a single signal for each protein-bound anion.

Overall, although subject to a successive reevaluation (see below), these ^{13}C NMR data strongly supported the bridging arrangement of the synergistic anion prior to publication of the X-ray data.^{2,3} Moreover, more recent ^{113}Cd NMR spectra of the ^{113}Cd –Otf derivative with glycine as the synergistic anion unequivocally indicated the binding of the amino group of the amino acid to the metal, fully in line with the interlocking sites model.³³

Observation of the magnetic coupling between an $I = \frac{1}{2}$ metal and the carbon atom of the anion in both metal sites yielded conclusive spectroscopic evidence of a direct metal–ion linkage. In particular, this was achieved by using ^{205}Tl and ^{113}Cd ions loaded in one or both metal sites (Figure 3).^{11,12,34} The 2J coupling constants are collected in Table 2.

Thallium–transferrin derivatives allowed a reevaluation of the binding mode of oxalate, and led to further insight into the chemistry of the ternary adduct in the protein sites. The ^{13}C NMR signals of bound oxalate in each site of the $^{205}\text{Tl}^{3+}$ derivatives of human Tf and Otf are split into a doublet of doublets due to carbon–carbon and thallium–carbon coupling.¹² The comparable values of the ^{13}C –metal coupling constants for the two oxalate carbons (Table 2) indicate that the anion binds to the metal in a 1,2-bidentate mode at both sites. This is likely to be the case for all the oxalate adducts of transferrins with tripositive metals, as recently suggested from the similarity of the ^{13}C NMR spectral patterns for these adducts.¹² This view receives conclusive support from the X-ray structure of the Cu^{2+} –oxalate ternary adduct with the C-terminal half-molecule of Ltf,³⁵ which confirms the 1,2-bidentate bridging arrangement of the oxalate anion and indicates that the spectral inequivalence of the two carbon

Table 2 Spectral Parameters for Metal NMR Resonances and M–¹³C Coupling Constants for Various Metal–Transferrin Derivatives^a

atoms in the ternary adducts with tripositive metals arises from differences in the protein residues H bonded to the two carboxylate groups. In the light of these results, the ¹³C spectra of the ¹¹³Cd²⁺–oxalate adduct of Otf, for which, unlike the carbonate derivative,¹¹ no ¹¹³Cd–¹³C coupling could be detected,³² consistent with a longer metal–carbon distance, can also be interpreted in terms of the above anion arrangement.

Recent work on NMR of quadrupolar metal nuclei (⁵¹V, ²⁷Al, and ⁴⁵Sc) (see *Aluminum-27 NMR of Solutions; Quadrupolar Transition Metal and Lanthanide Nuclei*) loaded in the sites of transferrins deserve a special mention.^{12,30,36–40} For an $I = \frac{n}{2}$ nucleus ($n = 3, 5, 7$) firmly bound to a slowly rotating macromolecule, far from the extreme narrowing limit, it is shown that only the central $\frac{1}{2} \rightarrow -\frac{1}{2}$ nuclear spin transition can be observed (see *Quadrupolar Interactions*) (Figure 4). Under these conditions the field dependence of the linewidth and chemical shift (see *Dynamic Frequency Shift*) provides the values of the quadrupole coupling constant, χ , and of the rotational correlation time, τ_c , for the protein-bound metals, and hence yields information

on the symmetry of the metal coordination environment. For example, independent of the synergistic anion, the Al³⁺ ion appears to be octahedrally coordinated in both sites, with a higher degree of symmetry in the N-site as compared to the C-site.³⁰ Moreover, the metal sites of the Sc³⁺–Otf derivative show a higher symmetry than those in the homologous Al³⁺ derivative.³⁸

Since detection of the resonances of these quadrupolar nuclei is facilitated by increasing the magnetic field and the molecular size of the protein, the technique is of general interest for probing the properties of the metal binding sites of large metalloproteins.

2.4 The (In)Equivalence of the Two Binding Sites

Early water proton relaxation measurements of Fe³⁺ binding to Otf, coupled with electrophoretic profiles, failed to detect the difference in iron binding ability of the two sites,⁴¹ indicating a random distribution of iron in the two lobes.¹⁴ Inequivalences can be detected with the aid of paramagnetic

Figure 2 75.4 MHz ^{13}C NMR spectra of the carbonyl region of (A) Otf-carbonate-metal complexes and (B) Otf-oxalate-metal complexes in the presence of excess anion, pH 8 (protein concentration 1.5 mM): (a) apoprotein; (b) Al^{3+} derivatives; (c) Ga^{3+} derivatives; and (d) Zn^{2+} derivatives. (Reproduced by permission of the American Chemical Society from I. Bertini, C. Luchinat, L. Messori, A. Scozzafava, G. C. Pellacani, and M. Sola, *Inorg. Chem.*, 1986, **25**, 1782)

metals like Co^{2+} ^{8,9} and lanthanides,⁴² taking advantage of the sensitivity of hyperfine shifts to even slight changes in the coordination sphere.¹⁰ The advent of high-field Fourier transform spectrometers allowed the safe determination of site (in)equivalence simply from the presence of either one or two NMR signals (or signal patterns) due to the ^{13}C -labeled synergistic anion and/or NMR-active diamagnetic metals bound to the protein. A metal titration then generally indicated if sequential metal binding had occurred, and in some instances assignment of the NMR resonances to the individual sites allowed the site with higher metal affinity to be determined. This approach has been followed for the derivatives of Otf and Htf with Co^{3+} , Ga^{3+} , Al^{3+} , Tl^{3+} , Sc^{3+} , V^{5+} , Cd^{2+} , Zn^{2+} in combination with different synergistic anions, most often carbonate and oxalate. The NMR-active metals and the ^{13}C -labeled synergistic anion loaded in the two sites led to either overlapping peaks or distinct, but invariably closely spaced, resonances indicative of equivalent (within the resolution available) or slightly different chemical environments, respectively (Table 1 and 2). The higher metal affinity of the C-site over the N-site at acidic pH was, in general, exploited to obtain resonance assignment to individual sites, although recently the use of proteolytically-obtained half-molecules has proved to be a safer means for such an assignment. This was evidenced for the derivatives of human Tf and Otf with Al^{3+} , Tl^{3+} , and Sc^{3+} , for which the metal resonances and the ^{13}C signals of the synergistic anion in the bimetallic derivative were invariably found to exactly superimpose the signals of the two one-sided half-molecules.^{12,30,36-38}

These extensive NMR data concurred to indicate that the relative properties of the two sites for a given transferrin vary with the nature of the metal, the synergistic anion, pH, and medium composition, and may differ from those of other transferrins. The following selected examples are worth mentioning. Aluminum-27 and ^{13}C NMR showed that in the presence of carbonate the two aluminum metal sites of Otf are slightly inequivalent and that Al^{3+} binds preferentially to the N-site at pH 8, while the site preference is reversed with oxalate.³⁰ In contrast, spectroscopically equivalent sites are detected in the homologous derivatives of human Tf and Ltf.³⁶ At pH values slightly above neutrality in the presence of carbonate, the Tl^{3+} ion was shown at an early stage,⁴³ unlike Al^{3+} , to bind more strongly to the C-site of human Tf, and more recently to bind with the same affinity to both sites of Otf.¹² Moreover, Sc^{3+} showed no site preference toward Otf with either carbonate or oxalate as synergistic anions,³⁸ and site inequivalence in the Cd^{2+} derivative of Tf with oxalate appeared more pronounced than in the homologous Zn^{2+} derivative.^{11,32}

Although this overview demonstrates NMR to be a powerful tool for probing the differences in structural properties and binding affinity of the two metal sites, at present, as noted elsewhere,⁴⁴ it does not address unequivocally the question of the presence of a functional association between the lobes. The above-mentioned near-identity of the spectral properties of a given site in the half and intact transferrin molecules does not necessarily imply that the metal affinity of the sites remains unchanged upon proteolytic cleavage.

The application of resolution enhancement techniques, although allowing resolution of only a small fraction of the total proton resonances, particularly those belonging

to relatively mobile portions of the protein, has recently enabled one- and two-dimensional ^1H NMR (see *COSY Two-Dimensional Experiments; Multidimensional Spectroscopy: Concepts; NOESY*) to monitor the binding of diamagnetic metals to whole and half-transferrin molecules.^{45–47} Low-frequency methyl peaks probably experiencing aromatic ring

current shifts, glycan *N*-acetyl and sugar ring protons, Lys/Arg $\epsilon/\delta\text{-CH}_2$ protons, and His C-2,H resonances could be resolved in the apo form of human Tf.⁴⁷ The disappearance of some of these peaks and the rise of new resonances in a slow exchange regime upon metal titration of the apo form of whole human Tf and its N-lobe (HTf/2N hereafter) allowed the detection of the sequential binding of Al^{3+} and Ga^{3+} to Tf, with preferential binding of the former metal to the N-site (in the presence of carbonate, pH 8.8),⁴⁶ and of the latter to the C-site (with oxalate as a synergistic anion, pH 7.2).⁴⁵ Examples of one- and two-dimensional proton spectra are illustrated in Figure 5.⁴⁵

Since X-ray data indicate that the structural features of the N-lobe are likely to be closely similar in the intact protein and in the isolated lobe,² the lack of a perfect match between the spectral features of the apo form and the Al^{3+} adducts of Tf and Tf/2N was interpreted as indicative of an interaction between the lobes in the intact protein.⁴⁶ This approach also allowed a determination of the apparent binding constant of oxalate to apo-HTf/2N ($\log K = 4.04 \pm 0.09$) from the shift of some resonances induced by the weak binding of the anion, as a consequence of the fast exchange between the free and anion bound species on the NMR timescale.⁴⁵ Moreover, the time course of the paramagnetic broadening of the proton resonances in the Ga^{3+} -oxalate-HTf/2N adduct upon Fe^{3+} addition allowed the kinetics of Ga^{3+} displacement ($k_{\text{obs}} = 0.162 \text{ h}^{-1}$ at 310 K) to be determined.⁴⁵

2.5 Other Structural Features in Solution

Tentative assignments of the low-frequency methyl proton resonances to individual Leu, Val, and Ile residues were proposed for human Tf and its N-lobe through 2D COSY techniques (see *COSY Two-Dimensional Experiments*) and calculation of the shifts induced by the ring currents of nearby aromatic groups (see *Shielding: Overview of Theoretical Methods*).^{45,46} The shifts of these resonances upon metal binding appear to be related to changes in their orientation toward the aromatic groups which reside in relatively mobile, yet structured hydrophobic domains possibly involved in conformational changes related to the closure of the interdomain cleft.⁴⁵ Unambiguous signal assignments and determinations of the precise movements of single residues are still unavailable, but much effort is being devoted toward this end.

Nonsynergistic anions like chloride, perchlorate, thiocyanate, and pyrophosphate are known to decrease the stability of various metal-transferrin derivatives, and, the chloride ion in particular, to affect the relative metal binding affinity of the sites.⁴⁸ They most probably bind to positively charged residues in the proximity of the metal site, altering the network of salt bridges and hydrogen bonds that stabilize the complex. The effect of perchlorate in decreasing the stability of the metal complexes was clearly monitored by the decrease of the ^{13}C and ^{113}Cd NMR resonances of the $^{113}\text{Cd}_2\text{-Otf-CO}_3^{2-}$ adduct upon anion addition, due to dissociation of the complex.¹¹ Chlorine-35 and ^{14}N NMR linewidth measurements of chloride, perchlorate, and nitrate anion binding to human Tf in a fast exchange regime allowed the determination of a 2:1 stoichiometry for V^{5+} binding to the protein, since the formation

of the ternary metal-carbonate complex at the sites determines the specific anion binding to the protein and hence leads to a decrease in quadrupolar relaxation (see *Relaxation Theory for Quadrupolar Nuclei*).⁴⁹

Proton NMR has also played an important role in the determination of the primary structure on the glycan moieties of a variety of transferrins and in the determination of solution conformation through 2D techniques.⁵⁰⁻⁵³ Studies were carried out on glycopeptides obtained by proteolytic digestion or on the intact oligosaccharide chain detached from the protein by hydrazinolysis. Readers are referred to the original literature as far as the assignment procedures are concerned. However, it is worth mentioning that recent ^1H NMR studies on Ga^{3+} binding to human Tf indicate that metal binding alters the shift of the resonances of the *N*-acetylated sugar residues of both glycan chains, suggesting that the transmission of the perturbation to the carbohydrate chains may have significance for cell receptor recognition of the metal-loaded protein.⁴⁵

3 THE ROLE OF NMR IN THE CHEMISTRY OF TRANSFERRINS: FUTURE PROSPECTS

The applicability of NMR techniques becomes less and less trivial with increase in molecular size. From this point of view, molecules of the size of transferrins represent a challenge. Multidimensional NMR, coupled with resolution enhancement techniques, of either intact and half-transferrin molecules, appear as a promising approach for detecting structural changes in the individual lobes upon metal uptake or release and ionization equilibria, and should be of use for monitoring the protein behavior toward the binding of a variety of metals and synergistic anions, under different conditions of pH and medium composition. The bottom line is to understand whether the two lobes undertake different roles in metal uptake and release processes, and whether they are functionally associated, and hence to address one of the most intriguing points of the biochemistry of transferrins related to their structural 'doubleness'. The advent of very high field spectrometers (750 MHz or higher) would greatly enhance the diagnostic power of this approach, together with the feasibility of NMR of quadrupolar metal nuclei which has proved highly sensitive to the structural features of the metal sites. The use of genetically-engineered proteins containing either amino acid substitutions, deletions, or labeled residues could also add essential information. Nitrogen-15 and/or ^{13}C selective and nonselective labeling is indeed providing a breakthrough to structural studies on medium sized proteins (see *Heteronuclear Assignment Techniques; Heteronuclear Shift Correlation Spectroscopy*).

Besides metal binding, NMR should also be a valuable means of monitoring the potential ability of transferrins to accommodate small molecules in the binding cleft.³ Overall, the application of ^1H NMR to determine protein structure in solution, coupled with molecular dynamics calculations (although the size of transferrin would set this as a long-term project) appears to be the main research direction toward the elucidation of the structure-function relationships in this class of proteins.

1 INTRODUCTION

The discovery in 1985 of ‘zinc-binding fingers’ in transcription factor IIIA from *Xenopus* oocytes^{1,2} stimulated the development of a new field in bioinorganic chemistry that ultimately led to the identification of several novel classes of zinc-containing nucleic acid interactive protein domains (NAIDs). The term ‘zinc finger’ has been generally used to describe any miniglobular zinc-containing protein domain that functions in nucleic acid interactive processes. The ‘classical CCHH’ zinc finger^{1,2} consists of a stretch of amino acids of the type: C-X₂-5-C-X₁₂-H-X₂-4-H (CCHH). Other zinc-containing NAIDs are often referred to as ‘nonclassical zinc fingers’. Examples of such nonclassical zinc finger domains that have been studied by NMR include

1. the CCHC type (C-X₂-C-X₄-H-X₄-C), observed originally in retroviral nucleocapsid proteins but more recently found in proteins from other organisms, including frogs and humans;³⁻⁵
2. the cysteine-rich DNA-binding domain of GAL-4 (C-X₂-C-X₆-C-X₆-C-X₂-C-X₆-C),⁶ which coordinates two atoms of zinc in a binuclear cluster that contains two bridging cysteines;
3. the steroid hormone receptor (SHR) family of DNA binding domains (DBDs),⁷ in which two zinc atoms are bound via cysteines in two structurally nonequivalent but interacting CCCC modules of the type, C-X₂-C-X₁₃-C-X₂-C and C-X₅-C-X₉-C-X₂-C;
4. the DNA-binding domain of GATA-1, which binds zinc via a C-X₂-C-X₁₇-C-X₂-C sequence;⁸
5. the RING motif, which binds two atoms of zinc in independent sites via a C-X₂-C-X₁₂-C-X-H-X₂-C-X₂-C-X₁₀-C-X₂-C (or C₃HC₄) sequence;⁹

6. the LIM motif, which also binds two equivalents of zinc in independent sites via a C-X₂-C-X₁₆-23-H-X₂-C-X₂-C-X₂-C-X₁₆-21-C-X₂-3-C/H/D (C₂HC₅) sequence;^{10,11}
7. the zinc ribbon motif observed in transcription elongation factor TFIIS that binds one atom of zinc in a C-X₂-C-X₂₅-C-X₂-C sequence;¹²
8. the zinc-containing domain of the tRNA synthetases;^{13,14}
9. the zinc site of bacteriophage T4 gene-32 protein;^{15,16}
10. the protein kinase C (PKC) zinc-binding domain;¹⁰¹
11. the DNA methyl phosphotriester repair domain of Ada.⁸²

Nuclear magnetic resonance spectroscopy has played a major role in advancing understanding of the structure and function of zinc-containing nucleic acid interactive domains. Indeed, the first structures of each class of zinc finger domain were determined originally by NMR methods, except for **GAL-4**, where the NMR^{17,18} and X-ray structures¹⁹ were reported simultaneously. Currently, there are at least 12 independent NMR structures reported for **CCHH** zinc finger domains,²⁰⁻²⁵ six NMR structures of **CCHC** zinc finger domains and **CCHC**-containing proteins,^{26-30,102} three NMR structures of the GAL-4-type DNA-binding domain,^{17,18,103} and five NMR structures reported for steroid hormone receptor DNA-binding domains.³¹⁻³⁵ The structure of a **CCHC** zinc finger–nucleic acid complex has also been determined by NMR.³⁶ More recently, structures have been determined for the DNA-binding domain of GATA-1⁸ and for the RING,⁹ PKC,¹⁰¹ Ada,⁸² and LIM³⁷ zinc-binding domains by NMR methodologies. In addition, X-ray structures have been reported for DNA complexes with the **CCHH**-containing DNA-binding domains of the transcription factors Zif-286³⁸ and GLI³⁹ and with the DNA-binding domains of the GAL-4¹⁹ and glucocorticoid receptor proteins.⁴⁰ In each of these domains, the essential zinc atoms do not participate directly in binding to nucleic acid, but rather function to stabilize a particular globular fold that allows amino acid side chains to make specific contacts with the nucleic acid.

The availability of structural data for a diverse class of zinc-containing NAIDs has enabled philosophical and experimental approaches to the question: why zinc fingers? Although current knowledge is not sufficient to address this question fully, one fact has become apparent; namely, all classes of Zn-NAIDs exist as highly stable, independently folded domains, despite the fact that the domains comprise a relatively small number of amino acid residues. Indeed, the **CCHC** retroviral-type motif comprises only 18 amino acid residues, and may represent the smallest known miniglobular protein domain. The ‘zinc finger’ motif thus appears to be Nature’s choice for establishing stable, folded, miniglobular protein domains comprising a minimal number of amino acid residues. This prompts the following question: Why are zinc finger domains so stable?

By examination of the structures determined thus far for the different classes of Zn-NAIDs, common structural elements can be identified that may serve as the primary determinants of stability.⁴¹⁻⁴³ Specifically, all known Zn-NAIDs exhibit extensive hydrogen bonding between backbone amide protons and the cysteine sulfur atoms that are coordinated to zinc. NH...S hydrogen bonding was observed originally by Adman and co-workers⁴⁴ in the iron-binding domains of rubredoxins and ferredoxins, and, perhaps surprisingly, many of the structural elements observed originally in the iron domains of the iron–sulfur proteins are also observed in the zinc sites of the Zn-NAIDs.

2 NH...S HYDROGEN BONDING AS A DETERMINANT OF STABILITY IN MINIGLOBULAR ZINC-CONTAINING NUCLEIC ACID INTERACTIVE DOMAINS (NAIDs)

As indicated above, all of the known Zn-NAIDs that have been structurally characterized thus far contain NH...S hydrogen bonds between specific backbone amide protons and Zn-coordinated cysteine sulfurs. The local structural elements observed are often very similar to those observed in the iron-binding domain of rubredoxin (Rd). All rubredoxins contain two copies of a conserved iron-binding sequence, $X_{(i-2)}-X_{(i-1)}-C_{(i)}-X_{(i+1)}-X_{(i+2)}-C_{(i+3)}-G_{(i+4)}-X_{(i+5)}$ (where X is a variable amino acid), and high-resolution X-ray and NMR structures of proteins from *Clostridium pasteurianum*, *Desulfovibrio gigas*, *D. vulgaris*, *D. desulfuricans*, and *Pyrococcus furiosus*, reveal that the four Cys residues are coordinated to the single iron atom. The backbone conformations of the N- and C-terminal X-X-C-X-X-C-G-X-X-X residues are essentially identical. Adman and co-workers⁴⁴ discovered that three of the backbone amide protons within each of the $C_{(i)}-X_{(i+1)}-X_{(i+2)}-C_{(i+3)}-G_{(i+4)}-X_{(i+5)}$ loops are involved in amide-to-sulfur hydrogen bonding. The backbone amide protons of residues $X(i+2)$ and $Cys(i+3)$ are oriented in the direction of the $Cys(i)$ side-chain sulfur atom, forming what are referred to as Types I and III tight turns, respectively (Figure 1). In addition, the backbone amide proton of residue $X(i+5)$ is oriented toward the side-chain sulfur atom of $Cys(i+3)$, forming a Type II NH...S tight turn. Rubredoxins also contain a conserved Gly residue at position $(i+4)$, and it was proposed that this residue is conserved in order to stabilize the Type II NH...S tight turn.⁴⁴ The glycine NH is positioned to hydrogen bond with the carbonyl of $Cys(i)$, forming a Type II NH...O bond. Throughout this article, this conserved folding pattern (Figure 1) will be referred to as an 'Rd knuckle'.

To gain insights into the nature of the NH-S hydrogen bonding, NMR studies have been performed on Zn-, ^{113}Cd -,

and ^{199}Hg -substituted rubredoxin from the extreme hyperthermophile, *Pyrococcus furiosus* (pf), a bacterium that grows optimally at 100 °C.^{41,45-47} The ^1H - ^{113}Cd heteronuclear spin echo difference (HSED) spectrum obtained for ^{113}Cd -PfRd exhibited four backbone NH signals corresponding to the Ile(7), Cys(8), Ile(40), and Cys(41) backbone NH protons, of which Ile(40) and Cys(41) are part of the metal-binding CXXCGX knuckle ($C_{38}-X-I_{40}-C_{41}-G_{42}-A_{43}$). The observed scalar couplings between ^{113}Cd and the NH protons of Ile(40) and Cys(41) do not occur through the peptide backbone, since the NH protons are eight and five bonds removed from the metal, respectively. The observed amide HSED signals are thus attributed to two-bond $^2J(^{113}\text{Cd}, ^1\text{H})$ scalar coupling mediated by NH...S(Cys) hydrogen bonds. These findings provide direct evidence that Types I and III NH...S hydrogen bonds exist in PfRd, and further demonstrate that these hydrogen bonds contain significant covalent character.

^1H - ^{199}Hg HSED NMR experiments were also performed on the ^{199}Hg adduct to evaluate the influence of this larger metal on the nature of the NH...S hydrogen bonds.^{41,47} A portion of the ^1H - ^{199}Hg HSED spectrum is shown in Figure 2. As observed for the ^{113}Cd adduct, HSED signals were observed for the Ile(7,40) and Cys(8,41) backbone NH protons,⁴⁵ confirming the presence of the Types I and III NH...S turns. Interestingly, the magnitudes of the scalar couplings, determined using a novel pulse sequence that affords pure-phase HSED spectra,⁴⁷ were approximately twofold greater than the coupling constants determined for ^{113}Cd -PfRd. This finding confirms that the HSED signals result from scalar coupling rather than from a dipolar cross-correlation mechanism. In addition, a weak ^1H - ^{199}Hg HSED signal [$^2J(^{199}\text{Hg}, ^1\text{H}) = 0.4\text{ Hz}$] was detected for the Tyr(10) backbone amide proton. Although a similar signal for the analogous Ala(43) amide could not be distinguished owing to signal overlap, the observation of a Tyr(10) NH HSED signal confirmed the existence of the Type II NH...S turn. Thus, for

Figure 1 Structure of a 'rubredoxin knuckle' showing NH...S hydrogen bonds from the backbone amide protons of residues $X(i+2)$ and $Cys(i+3)$ to the S- γ sulfur of residue $Cys(i)$, and from the backbone amide proton of residue $X(i+5)$ to the S- γ sulfur of residue $Cys(i+3)$. This folding pattern, which was observed originally in the iron-binding site of rubredoxin,^{44,100} is commonly found in the zinc-binding sites of zinc fingers

Figure 2 Portions of an ^1H - ^{199}Hg heteronuclear spin echo difference spectrum obtained for ^{199}Hg -substituted rubredoxin from the hyperthermophile *P. furiosus*.⁴⁷ Difference signals are observed for backbone NH protons involved in Types I, II, and III NH...S hydrogen bonding, confirming the presence of these hydrogen bonds and demonstrating that these bonds contain significant covalent character

the ^{199}Hg adduct, where the magnitudes of the scalar couplings are greatest, HSED spectroscopy provided confirmation for the existence of all three types of $\text{NH}\cdots\text{S}$ tight turns (Figure 1).

As a side note, ^1H - ^{113}Cd and ^1H - ^{199}Hg scalar coupling was also observed between the metal and the Ala(43) methyl protons (Figure 2).^{41,45,47} This scalar coupling is probably due to direct orbital overlap between the methyl protons of Ala(43) and the Cys(42) sulfur atom, since 6- and 11-bond ^1H - ^{113}Cd scalar coupling mediated by the Ala(43) $\text{NH}\cdots\text{S}$ hydrogen bond or by the covalent bonds, respectively, is implausible. This finding has important implications for understanding intraprotein electron transfer, since (a) it suggests that 'through-space electron jumps' may be energetically more favorable than previously expected,⁴⁸⁻⁵² and (b) $\text{CH}_3\cdots\text{S}(\text{Cys})$ overlap provides a direct electron transfer pathway between the metal center and the hydrophobic core of the protein.

3 CLASSICAL CCHH ZINC FINGERS

To date, more than a dozen classical **CCHH** zinc finger domains have been structurally characterized by NMR and X-ray crystallographic methods.²⁰⁻²⁵ Except for a few cases, the experimentally derived **CCHH** zinc finger structures are consistent with a structure predicted on the basis of sequence comparisons with other metalloproteins, including rubredoxin.⁵³ Klevit and co-workers⁵⁴ were the first to provide experimental NMR evidence in support of the predicted model, and shortly thereafter, atomic coordinates for a peptide with sequence of the 31st zinc finger of the *Xenopus* protein, Xfin, were published by Wright and co-workers.²⁰

The **CCHH** zinc finger consists of a three-turn helix and a short antiparallel β -sheet. The strands of the β -sheet are linked by the **CXXCXX** metal-binding turn. The **CXXCXX** turns for five representative **CCHH** zinc finger structures are shown in Figure 3. For comparison, relevant residues of the N-terminal **CXXCXX** turn of *C. pasteurianum* Rd, and the associated $\text{NH}\cdots\text{S}$ and $\text{NH}\cdots\text{O}$ hydrogen bonds, are included in this figure. These residues within zinc fingers Xfin-31, ADR-1 and Zif286-2,3 are folded in a manner similar to the folding of analogous residues in rubredoxins. All of these structures exhibit the Types I and III $\text{NH}\cdots\text{S}$ hydrogen bonding found in rubredoxins. However, only the zinc fingers of ADR1b and Zif-268 exhibit the Type II $\text{NH}\cdots\text{S}$ turn after the second Cys. The $\text{C}_{(i+3)}\text{-X-X}$ residues of the Xfin-31 structure were disordered, precluding classification of the potential $\text{NH}\cdots\text{S}$ hydrogen bonding for the $\text{X}(i+5)$ amide proton.

The **CXXCXX** loops of the Zif-268 and ADR-1 zinc fingers contain Type II $\text{NH}\cdots\text{S}$ turns after the second cysteine, whereas finger-3 of Zif-268 contains a Gly residue at position $(i+4)$. Finger-2 of Zif-268 and the ADR-1 zinc finger contain Met and Thr residues, respectively, at position $(i+4)$. Type II folding results in a positive ϕ value for the residue at position $\text{X}(i+4)$, and, as such, it was proposed early on that Type II $\text{NH}\cdots\text{S}$ folding should be stabilized by a glycine residue at position $\text{X}(i+4)$. This provided a rationale for the conservation of glycine residues at position $\text{X}(i+4)$ in the **CXXCXX** loops of all known rubredoxins.⁵⁵ As shown in Figure 1, Type II $\text{NH}\cdots\text{S}$ folding leads to hydrogen bonds between the $\text{X}(i+4)$ amide proton and the $\text{Cys}(i)$ carbonyl and

Figure 3 Comparison of the folding of the **CXXCXX** residues of representative classical-type **CCHH** zinc fingers with related residues of rubredoxin.¹⁰⁰ The folding of these residues in the Xfin-31,²⁰ ADR1b,²⁵ and Zif-268-2³⁸ zinc fingers is essentially identical to that observed in the X-ray structure of *C. pasteurianum* Rd. The ZFY-even finger domain²²⁻²⁴ is similar, except that residues $\text{C}_{(i+3)}\text{-X}_{(i+4)}\text{-X}_{(i+5)}$ form a Type I $\text{NH}\cdots\text{S}$ turn. The zinc fingers of the human enhancer DNA-binding domain²¹ are unusual in that (i) the χ_1 value of the $\text{Cys}(i+3)$ residue precludes the formation of an $\text{NH}\cdots\text{S}$ hydrogen bond between the amide proton of $\text{X}(i+5)$ and the $\text{Cys}(i+3)$ sulfur, and (ii) the amide proton of $\text{X}(i+2)$ does not appear to form a hydrogen bond to the $\text{Cys}(i)$ sulfur

between the $\text{X}(i+5)$ amide proton and the $\text{Cys}(i+3)$ sulfur. Thus, the unfavorable steric interactions associated with the positive ϕ value may be offset by the additional hydrogen bond formed between the $\text{X}(i+4)$ amide and the $\text{Cys}(i)$ carbonyl.⁴⁴ A positive ϕ value has also been observed for the Type II $\text{NH}\cdots\text{S}$ turn of residues C-A-G in the iron site of ferredoxin, where the Ala methyl group eclipses the Cys carbonyl.⁴⁴

The amide proton of the $\text{X}(i+5)$ residue of the ZFY-even finger and an even finger mutant are directed toward the β -carbon of the $\text{Cys}(i)$ residue and not toward the sulfur atoms of residue $\text{Cys}(i+3)$.²²⁻²⁴ In addition, the $\text{Cys}(i+3)$ -to- $\text{X}(i+4)$ peptide bond is oriented in a manner that would preclude hydrogen bonding to the $\text{Cys}(i)$ carbonyl (Figure 3). Thus, although the folding observed for residues C-X-X-C of the ZFY-even finger domains are consistent with the rubredoxin fold, the conformation of the $\text{C}_{(i+3)}\text{-X-X}$ residues differs from that observed in rubredoxins. The folding observed for the zinc finger domains of the human enhancer protein DNA-binding domain (hEBP)^{21,56} are unusual in that the side-chain orientation of the $\text{Cys}(i+3)$ residues precludes formation of a Type II $\text{NH}\cdots\text{S}$ turn, and amide orientations are generally inconsistent with $\text{NH}\cdots\text{S}$ hydrogen bonding.

In summary, with the exception of the human enhancer protein DNA binding domain, all of the classical **CCHH** zinc

finger structures exhibit Types I and III $\text{NH}\cdots\text{S}$ hydrogen bonds within the C-X-X-C knuckles. In addition, all **CCHH** zinc fingers except those of the hEBP and ZFY-even zinc finger domains exhibit an $\text{NH}\cdots\text{S}$ hydrogen bond from the $\text{X}(i+5)$ backbone amide to the $\text{Cys}(i+3)$ sulfur, forming either a Type I or II $\text{NH}\cdots\text{S}$ turn.

4 RETROVIRAL CCHC ZINC FINGERS

Retroviral genes encode a gag precursor polypeptide that functions in the recognition of viral RNA and in the assembly of virus particles.^{57,58} Subsequent to assembly and budding, the gag polypeptides are cleaved by the viral protease to smaller proteins, including the nucleocapsid (NC) proteins. In 1981, Henderson and co-workers⁵ at the Frederick Cancer Research and Development Center showed that retroviral gag and NC proteins contain at least one copy of an invariant amino acid sequence, C-X₂-C-X₄-H-X₄-C. This conserved sequence has recently been found in proteins ranging from plant viruses to frogs to humans, and thus may represent a common motif for binding single stranded nucleic acids.⁵⁹ For example, a nine tandem repeat of the conserved sequence is found in a protein encoded by the *Leishmania major* gene of the protozoan parasite *Leishmania*;⁶⁰ a seven-tandem repeat is found in human cellular nucleic acid binding protein (hCNBP) that binds to the sterol regulatory element;⁶¹ and a single motif is present in a protein encoded by the *Xenopus-Posterior* (*Xpo*) gene of frog embryos.⁶²

NMR structures have been determined for peptides with sequences of several **CCHC** zinc finger domains, as well as for the intact NC protein from HIV-1.^{27–30,63} Like TFIIIA, overall folding of the NC protein consists of the independent **CCHC** zinc finger domains separated by a labile linker region. The global folding **CCHC** Zn-NAIDs consists of a short antiparallel β -sheet with an Rd knuckle, followed by a short β -like stretch that precedes a 3_{10} helix. Like **CCHH** zinc fingers and rubredoxin, the metal binding site of **CCHC** NAIDs fold with a number of $\text{NH}\cdots\text{S}$ hydrogen bonds, including a hydrogen bond between the side-chain NH of $\text{Asn}(i+2)$ and the $\text{Cys}(i+3)$ sulfur, and between the backbone NH protein of residue $\text{X}(i+15)$ and the $\text{Cys}(i+13)$ sulfur. In addition to these five $\text{NH}\cdots\text{S}$ hydrogen bonds, there are a total of six $\text{NH}\cdots\text{O}$ hydrogen bonds that further stabilize the **CCHC** zinc finger structure.⁴²

5 STEROID HORMONE RECEPTOR DNA-BINDING DOMAINS

The steroid hormone receptor (SHR) superfamily is a class of transcription regulatory proteins whose activity is controlled by the binding of specific hormones. This class so far comprises more than a dozen proteins, including the glucocorticoid receptor, retinoic acid receptor β , progesterone receptor, estrogen receptor, and retinoid X receptor- α proteins. Typically, members of the SHR family bind as dimers to specific DNA hormone response elements (HREs),⁶⁴ forming a hormone–receptor complex that activates transcription.⁶⁵ To date, three-dimensional structures have been determined by NMR for five steroid hormone receptor DNA-binding

Figure 4 Comparison of the folding of the CXXCXX residues of the glucocorticoid receptor DNA-binding domain with related residues of *C. pasteurianum* Rd.¹⁰⁰ The GR protein contains three CXXCXX arrays. The folding of the N-terminal array (GR: CXXCXX # 1) is very similar to that observed in rubredoxins. The remaining arrays contain Types I and III $\text{NH}\cdots\text{S}$ turns within the CXXC knuckles common to rubredoxins; however, the $\text{C}_{(i+3)}\text{-X-X}$ residues do not form an $\text{NH}\cdots\text{S}$ turn, because of their involvement in α -helical conformations. Interestingly, the amide proton of residue $\text{X}(i+4)$ participates in a hydrogen bond to the $\text{Cys}(i)$ carbonyl—an interaction that also occurs in rubredoxins

domains,^{31–35} and an X-ray structure of a DNA complex with the glucocorticoid receptor DNA binding domain has been reported.⁴⁰

The steroid hormone receptor (SHR) DNA-binding domains contain two independent zinc sites, with each of the zinc atoms coordinated via four cysteine residues. Unlike classical **CCHH** zinc fingers, the two zinc atoms are incorporated into a single domain, with several contacts between residues that comprise the independent zinc sites. The N-terminal zinc coordination site of the SHR proteins contains two CXXC arrays, and the C-terminal zinc site contains one CXXC array. Luisi et al.⁴⁰ indicated that several backbone amide protons are involved in $\text{NH}\cdots\text{S}$ hydrogen bonding to the metal-coordinating sulfurs. Comparison of the three CXXC segments reveals a variation in χ_1 values of the cysteine side chains, with only the N-terminal knuckle exhibiting a $\text{Cys}(i)$ side-chain orientation similar to that of rubredoxins (Figure 4). The backbone folding within each of the CXXC knuckles is generally consistent with the folding observed in rubredoxins, with backbone amide protons participating in Types I and III $\text{NH}\cdots\text{S}$ hydrogen bonding. The $\text{C}_{(i+3)}\text{-X-X}$ residues of the N-terminal CXXC knuckle form a Type II $\text{NH}\cdots\text{S}$ turn, with the $\text{X}(i+4)$ amide forming a hydrogen bond to the $\text{Cys}(i)$ backbone carbonyl. The $\text{C}_{(i+3)}\text{-X-X}$ residues of the two subsequent CXXC segments do not form $\text{NH}\cdots\text{S}$ turns, owing to the fact that these residues reside within an α -helix (Figure 4). To summarize, the N-terminal CXXCXX array forms an Rd knuckle with Types I, II, and III $\text{NH}\cdots\text{S}$ turns, and the two subsequent arrays are similar in that they contain the Types I and III $\text{NH}\cdots\text{S}$ turns within the CXXC segment, but differ in that (i) the χ values of the $\text{Cys}(i+3)$ side chains are significantly different, and (ii) the $\text{C}_{(i+3)}\text{-X-X}$ residues do not form an $\text{NH}\cdots\text{S}$ turn.

Figure 5 Comparison of the folding of the CXXCXX residues of the GAL-4 DNA-binding domain with related residues in *C. pasteurianum* Rd.¹⁰⁰ The folding of these residues is actually very similar to that observed for the two N-terminal CXXCXX stretches in the glucocorticoid receptor DNA-binding domain (see Figure 4)

6 GAL-4 DNA-BINDING DOMAIN

GAL-4 is a yeast transcription activator that binds to an upstream activating sequence (UAS_G) for the genes (*GAL-1* and *GAL-10*) encoding galactose-metabolizing enzymes.¹⁹ The 881-amino-acid residue GAL-4 protein binds as a dimer to the UAS_G-DNA site.⁶⁶ In the absence of galactose, GAL-4 remains on the DNA, but is inactivated by a complex formed with another protein, GAL-80.^{67,68} In the presence of galactose, a metabolite derived from galactose binds to and dissociates GAL-80, thus activating GAL-4.⁶⁶ The DNA-binding domain of GAL-4 is a 62-amino-acid sequence located on the N-terminus of the protein.¹⁷ This sequence contains a cysteine-rich array, C-X₂-C-X₆-C-X₆-C-X₂-C-X₆-C, which is conserved among 13 known fungal transcription factors.¹⁷ Unlike other Zn-NAIDs, the two zinc atoms of GAL-4 form a binuclear cluster that contains two bridging cysteines.^{17,69}

Structures of the GAL-4 NAIDs have been determined by NMR,^{17,18} and X-ray crystallographic¹⁹ methods. The GAL-4 DBD contains two helix–turn–strand motifs that are packed around the Zn(II)₂Cys₆ binuclear cluster.¹⁷ The structure has a twofold pseudosymmetry axis that passes between the two helices and the center of the Zn(II)₂Cys₆ binuclear cluster. The GAL-4 zinc-binding domain contains two CXXC arrays that participate in metal coordination. Both the N- and C-terminal CXXC arrays exhibit backbone folding that is generally consistent with the folding observed in rubredoxins. Amide protons of residues X(*i* + 2) and Cys(*i* + 3) are oriented in a manner consistent with Types I and III NH···S hydrogen bonding to the Cys(*i*) sulfur (Figure 5). However, the χ_1 values of the Cys side chains differ from those of Rd by almost 180°. The C_(*i*+3)-X-X residues comprise the N-terminal portions of α -helical stretches, and the associated backbone conformations preclude the formation of Type II NH···S turns. The folding of these residues is similar to that observed for analogous residues in the steroid hormone receptor proteins where an α -helical conformation exists (Figure 4).

7 GATAa-1 DNA-BINDING DOMAIN

The DNA-binding domain of the transcription factor GATA-1 contains two conserved zinc binding sequences of the form C-X₂-C-X₁₇-C-X₂-C. Mutational studies indicated that the N-terminal motif may be unimportant for specific

DNA binding,^{70,71} although more recent studies indicate that sequence specificity is a function of both domains.⁷²

The solution structure of the C-terminal GATA-DBD (residues 158–223) was determined recently by NMR methods.⁸ The global folding of the peptide consists of a core (residues 2–51) that contains the zinc binding region, and an extended C-terminal tail (residues 52–59).⁸ The folding of the majority of the core (residues 3–39) is very similar to the folding exhibited by the N-terminal CCCC zinc module of glucocorticoid receptor protein.⁸ Interestingly, both the GATA-1 domain and the N-terminal CCCC module of GR participate directly in protein–nucleic acid interactions.

The N-terminal CXXCXX array of GATA-1 forms a classical Rd knuckle that contains Types I, II, and III NH···S turns. The Type II turn is present despite the fact that the array lacks a Gly residue at position X(*i* + 4). In addition, the backbone NH of residue Cys(*i* + 21) forms a hydrogen bond to the Cys(*i*) sulfur, and the sulfur of Cys(*i* + 21) accepts a hydrogen bond from the backbone amide proton of Cys(*i* + 24).

8 MET-tRNA SYNTHETASE

Aminoacyl-tRNA synthetases are responsible for the correct esterification of tRNAs with the corresponding amino acid during protein translation.⁷³ A number of aminoacyl-tRNA synthetases have been analyzed and shown to display a zinc finger domain of the type C-X₂-C-X₉-C-X₂-C.⁷⁴ Among these enzymes are the methionyl-tRNA (met-tRNA), alanyl-tRNA, and isoleucyl-tRNA synthetases, all of which have been shown to contain zinc.^{75–77} On the other hand, tyrosyl- and phenylalanyl-tRNA synthetases, which do not contain zinc finger domains, apparently do not contain zinc.⁷⁸

Dardel and co-workers⁷³ have recently determined the three-dimensional structure of a peptide corresponding to the zinc coordination site of met-tRNA synthetase by NMR methods. The structure differs significantly from that determined by X-ray crystallography for the intact protein. The zinc binding site is located within residues 138–163 of the protein, and contains a single zinc atom coordinated via four cysteine residues. Unlike other Zn-NAIDs, the zinc binding region of met-tRNA synthetase does not contain any distinguishable helices or extended β -sheet structure. Instead, the domain contains a series of four consecutive tight turns separated by short loops. Turns 2 and 4 form Rd knuckles. Superposition of the backbone and Cys side-chain atoms of the XCXXCX residues of the met-tRNA synthetase metalloprotein with analogous residues of *C. pasteurianum* Rd and Zn(HIV-1-F1) afforded RMSD values of 65–90 pm.⁷³ The backbone amide protons of residues X(*i* + 2) and Cys(*i* + 3) are oriented in a manner consistent with Types I and III NH···S hydrogen bonding. The N- and C-terminal Rd knuckles contain Gly and Lys residues, respectively, at position (*i* + 4). As expected, the backbone amide of residue X(*i* + 5) from the CXXCGX array forms a hydrogen bond to the Cys(*i* + 3) sulfur, with the backbone amide proton of Gly(*i* + 4) forming a hydrogen bond to the Cys(*i*) carbonyl. Thus, the C_(*i*+3)-G_(*i*+4)-X_(*i*+5) residues exist in a Type II NH···S turn common to rubredoxins.

The backbone amide proton of the X(*i* + 5) residue from the N-terminal CXXCXX array also appears to form a hydrogen bond with the Cys(*i* + 3) sulfur. In addition, the backbone

amide proton of the lysine at position ($i + 4$) is oriented in the general direction of the Cys(i) backbone carbonyl. As such, the lysine at position ($i + 4$) possesses a positive ϕ value characteristic of Type II NH $\cdots$ S tight turns. Thus, as observed in the zinc finger of Zif-268-F2 and ADR1b, the presence of a nonglycine residue at position X($i + 4$) does not preclude the formation of a Type II NH $\cdots$ S turn.

9 TRANSCRIPTION ELONGATION FACTOR (TFIIS)

Transcription elongation factor TFIIS is a protein that binds to the large subunit of RNA polymerase II in a paused elongation complex, and allows elongation through DNA pause and termination sites. It also facilitates transcription of sites blocked by sequence-specific DNA-binding proteins.⁷⁹ The 50-amino-acid zinc binding domain contains a C-X₂-C-X₂₅-C-X₂-C motif. The structure of a peptide with sequence of the TFIIS zinc binding site (residues 235–280) was determined recently by NMR methods.⁸⁰ Unlike other Zn-DBDs, the domain does not contain α -helical structure, but consists of a three-stranded antiparallel β -sheet. Two of the sheets are located between the C(15)-X₂₅-C(40) region, while the third exists after the second C(40)-X₂-C(43) array. TFIIS also contains three β -turns (residues 14–16, 30–32, and 42–44) two of which contain the zinc-binding cysteines.⁸⁰ The zinc atom is chelated via two Rd knuckles, both of which contain Types I, II, and III NH $\cdots$ S turns [residues C₍₁₂₎-X₂-C₍₁₅₎-X-X and C₍₄₀₎-X₂-C₍₄₃₎-G-Asp(45)]. The N-terminal Rd knuckle contains a Type II NH $\cdots$ S turn, even though the sequence lacks a glycine at residue 16.

10 DNA METHYL PHOSPHOTRIESTER REPAIR DOMAIN OF ADA

The Ada protein from *Escherichia coli* repairs methylated DNA by direct, irreversible transfer of a phosphotriester methyl group to a cysteine residue. The nucleophilic activity of the cysteine sulfur appears to be promoted by coordination to zinc.⁸¹ Upon methylation, Ada binds specifically to DNA genes that confer resistance to methylating agents. The structure of an N-terminal 10 kDa fragment of Ada was determined by NMR methods.⁸² This fragment, which retains DNA methyl phosphotriester repair activity, contains a single atom of zinc and exhibits a folding pattern that is unique by comparison with other known zinc finger domains. The structure consists of a three-stranded antiparallel β -sheet sandwiched between two α -helices. The atom of zinc is bound tetrahedrally by four cysteines, including the active-site Cys(69). Interestingly, no evidence was found for the presence of NH $\cdots$ S hydrogen bonds. Thus, the backbone NH protons of residues near the sulfur atoms exhibited disorder and/or NH $\cdots$ S distances incompatible with NH $\cdots$ S hydrogen bonding, and none of these protons exhibited slow chemical exchange with water protons. Such hydrogen bonding might be expected to decrease the negative charge density on the cysteine sulfurs and render the active-site cysteine a poorer nucleophile.⁸² It will be very interesting to determine if the methylated form of the protein contains NH $\cdots$ S hydrogen bonds, since it is this form that exhibits sequence-specific DNA-binding properties.

11 RING FINGER

Over the past several years, more than 40 proteins have been identified from organisms including plants, fungi, viruses, and vertebrates that contain a 'C₃HC₄' or 'RING finger' motif (C-X₂-C-X₁₂-C-X-H-X₂-C-X₂-C-X₁₀-C-X₂-C).^{83,84} Proteins that contain a C₃HC₄ motif are involved in numerous processes, including transcription, site-specific recombination, differentiation, and oncogenesis.⁸⁵

The three-dimensional solution structure of a peptide of the sequence encompassing the C₃HC₄ domain from a herpes virus protein was recently solved by Barlow and co-workers.⁸⁶ The two zinc atoms are bound in separate sites, with Cys(8) and (11) and Cys(29) and (32) coordinating to one zinc, and Cys(29), (43), (46) and His(26) coordinating to the second zinc atom. The peptide binds two zinc atoms and adopts a $\beta\beta\alpha\beta$ structure. Barlow and co-workers showed that the amphipathic α -helix is essential for *trans*- activation of gene expression. Interestingly, the N-terminal $\beta\beta\alpha$ portion of the protein is structurally very similar to that of classical CCHH zinc fingers.⁸⁶ Several backbone NH protons appear to be oriented to allow NH $\cdots$ S hydrogen bonding with the metal-coordinating cysteines.

12 LIM MOTIF

A number of proteins with diverse functions and sub-cellular distributions display from one to three copies of a cysteine- and histidine-containing sequence called the LIM motif (C-X₂-C-X_{16–23}-H-X₂-C-X₂-C-X₂-C-X_{16–21}-C-X₂-3-C/H/D). This motif was first identified in three developmentally regulated transcription factors, *C. elegans* Lin-11, rat Isl-1, and *C. elegans* Mec-3.^{10,11} Each of these gene products exhibits two copies of the LIM motif plus a DNA-binding homeodomain and potential transcriptional activation domains.^{10,11} In addition to a growing collection of LIM homeodomain proteins,^{10,11,87–90} the LIM motif is also found in a number of proteins that lack additional DNA-binding sequences.^{91–96} For example, a cytoskeletal cysteine-rich protein (CRP) that has been implicated in cell growth control and differentiation contains two LIM domains as predominant sequence elements.^{95,97,98} CRP interacts with another LIM protein called zyxin, which is co-localized with CRP in association with the actin cytoskeleton, particularly at sites of cell–substratum adhesion.^{93,95} It has been postulated that zyxin and CRP may mediate communication between the cell membrane and the nucleus.⁹³

The C₂HC₅ LIM domain comprises tightly packed CCHC and CCCC zinc-binding modules. The folding and metal binding mode differ significantly from that of the C₃HC₄ RING finger motif, which also binds two atoms of zinc via seven cysteines and a histidine residue.^{9,99} The C-terminal CCCC module of the LIM domain folds in a manner essentially identical to that observed for the DNA-interactive CCCC modules of the GATA-1 and GR DBDs. Although previous biochemical studies have suggested that LIM domains may participate in protein–protein rather than protein–DNA interactions,⁹³ the demonstration that the LIM domain contains a substructure that is closely related to those of well-characterized DNA-binding domains raises the

possibility that the LIM domain may function in nucleic acid binding as well.

Heteronuclear spin echo difference (HSED) spectra were obtained for ^{113}Cd -substituted LIM to probe for $\text{NH}\cdots\text{S}$ hydrogen bonding. Scalar coupling was observed between the backbone NH protons of residues Lys(147), Cys(148) and Lys(150) and ^{113}Cd in the CCCC site, and between the backbone NH proton of Arg(120) and ^{113}Cd in the CCHC site, supporting the NOE evidence that these residues form Rd knuckles. These and additional $\text{NH}\cdots\text{S}$ hydrogen bonding patterns are similar to those observed in the GATA-1 DNA-binding domain.

13 SUMMARY

All of the zinc finger structures reviewed in this article contain at least one copy of a CXXC sequence at the metal binding site. As indicated above, many of these segments adopt similar backbone conformations when bound to zinc, with the NH protons of residues $\text{X}(i+2)$ and $\text{Cys}(i+3)$ oriented in a manner consistent with hydrogen bonding to the $\text{Cys}(i)$ sulfur. In addition, many of the structures exhibit Type II $\text{NH}\cdots\text{S}$ folding for the subsequent $\text{C}_{(i+3)}\text{-X}_{(i+4)}\text{-X}_{(i+5)}$ residues. In fact, for most Zn-NAID structures, the folding of at least one CXXCXX segment matches that of the analogous iron-chelating residues in rubredoxins. The formation of a Type II $\text{NH}\cdots\text{S}$ turn by residues $\text{C}_{(i+3)}\text{-X}_{(i+4)}\text{-X}_{(i+5)}$ clearly does not depend on the presence of a Gly at position $\text{X}(i+4)$, even though the ϕ value for the $\text{X}(i+4)$ residue in a Type II $\text{NH}\cdots\text{S}$ turn is positive. The $\text{NH}\cdots\text{O}$ hydrogen bond between the $\text{X}(i+4)$ amide and the $\text{Cys}(i)$ backbone carbonyl apparently compensates for the unfavorable steric interactions between the $\text{X}(i+4)$ side chain and the $\text{Cys}(i+3)$ carbonyl.⁴⁴ In several cases, the CXXCXX residues form a 'helix cap' at the N-terminal end of a helix. These structures still exhibit Types I and III $\text{NH}\cdots\text{S}$ turns within the CXXC segment, although the conformation of the subsequent residues precludes formation of a Type II $\text{NH}\cdots\text{S}$ hydrogen bond.

Heteronuclear ^1H -metal correlated NMR studies of ^{113}Cd - and ^{199}Hg -substituted forms of *P. furiosus* rubredoxin have provided the most detailed insights into the nature of the $\text{NH}\cdots\text{S}$ hydrogen bonds in the metal center. Protons that participate in Types I, II, and III $\text{NH}\cdots\text{S}$ hydrogen bonding exhibit $\text{NH}\cdots\text{S}$ hydrogen-bond-mediated scalar coupling, providing direct evidence that these protons are indeed hydrogen bonded to the cysteine sulfurs and demonstrating that the $\text{NH}\cdots\text{S}$ hydrogen bonds contain significant covalent character. $\text{NH}\cdots\text{S}$ hydrogen-bond-mediated scalar coupling has also been observed in a ^{113}Cd -substituted LIM domain for NH protons with sufficiently long T_2 values.³⁷ $\text{NH}\cdots\text{S}$ hydrogen-bond-mediated scalar coupling has been observed by Gardner, Coleman, and co-workers (personal communication) for ^{113}Cd -GAL-4.¹⁰³ Future studies with other classes of zinc domains are likely to lead to similar findings for what appear to be important determinants of stability in miniglobular Zn-NAIDs.

1 INTRODUCTION

In the study of biologically active molecules, the effectiveness of NMR spectroscopy is limited by proton resolution. Even using modern techniques with ^{13}C - and ^{15}N -labeled molecules of uniform enrichment the upper molecular weight limit for NMR applications is ca. 40 kDa. Site specific or ligand labeling methods are the only alternative for systems over this 40 kDa limit, and are most useful in the study of catalytic or dynamic regions of macromolecules. These latter approaches eliminate the resolution and assignment limitations of uniform labeling while bringing to bear the power of NMR for the study of structural and dynamic problems.

Tritium is the most attractive NMR active nucleus available for site specific or ligand labeling. We have included some chemical and radiochemical properties of tritium in Table 1 and compared the NMR characteristics of ^3H with ^1H , ^{13}C , and ^{15}N in Table 2. Among the most important NMR properties of tritium are the high gyromagnetic ratio and low spin number ($\frac{1}{2}$), yielding the highest molar sensitivity of any nucleus. This is important in biological systems where sensitivity is limited by low solubility and/or catalytic yield of biological molecules. The low natural abundance of tritium ensures that the ‘tritium window’ on biological systems is not clouded by spurious signals, and few published ^3H NMR spectra have more than a half dozen signals to assign and monitor. Assignment is aided by the fact that tritons and protons have essentially identical chemical shifts.¹ Replacing one isotope of hydrogen with another allows basically native species to be studied by tritium NMR spectroscopy. In contrast, labeling with ^{19}F or some different *element* can completely change the substrate under investigation. In general, labeling with tritium leads to minor isotope effects on the labeled system, and the most serious, kinetic isotope effects, may be helpful in unraveling the mechanism of reactions at the labeled site (as discussed below).

Despite its many advantages, tritium NMR development has lagged behind that of other heteronuclei. Initially, hardware development and concern over highly radioactive samples hindered progress. Indeed, the first recorded tritium NMR spectra required many TBqs (curies) of material to obtain an adequate signal. Modern high-field spectrometers can readily detect 3.7 MBq (0.1 mCi) of tritium (i.e. ca. 2.5×10^{15} nuclei). This makes radiation safety a less dominant issue and yields

a detection limit more suitable for biological samples. To contain the radiation, samples are often doubly sealed in Teflon tubes inside glass tubes. Since tritium is a weak β emitter ($E_{\text{max}} = 18.6 \text{ keV}$), this approach totally blocks radiation while providing insurance against leakage or spilling of samples.¹ To understand the amounts of radioactivity typically encountered in tritium NMR experiments one must be familiar with the commonly used units, which are included in Table 1 along with several conversion factors. The most important equivalence is: 100% substitution of a tritium atom for a hydrogen atom in a molecule leads to a specific activity of $1064 \text{ GBq mmol}^{-1}$ ($28.76 \text{ Ci mmol}^{-1}$). For example, 250 μL of a 1 mM solution (0.25 μmol) of a substrate having 100% abundance of tritium at a single site contains ca. 266 MBq (7.2 mCi). For perspective, safety lights in aircraft have up to 370 GBq (10 Ci) of tritium, a marine compass may contain as much as 28 GBq (0.75 Ci), and commonly available night sights for rifles contain 2 GBq (50 mCi) of tritium.

The sensitivity of the tritium nucleus in modern spectrometers, coupled with advances in synthetic labeling techniques, have paved the way for the use of tritium NMR in biology. Today, most small biologically active molecules can be readily tritium-labeled, and the chemistry is often more straightforward than labeling the same molecule with either ^{13}C or ^{15}N . The tritiated molecules can be studied in conjunction with macromolecules in virtually any biological system accessible by NMR spectroscopy, including solutions of proteins and nucleic acids, cellular suspensions, and whole animals. Tritium NMR spectra can provide a remarkably simple and revealing window into the structure, chemistry, and dynamics of a biological system.

Three general applications of ^3H NMR are discussed below: Section 2 will cover enzyme mechanistic studies; Section 3 will review enzyme ligand interactions; and Section 4 will discuss macromolecular labeling.

2 ELUCIDATION OF ENZYME STEREOCHEMISTRY

For decades, radioactive tracer nuclei such as ^{14}C , ^3H , ^{32}P , and ^{35}S have been used to study metabolic pathways in cells by determination of the radiolabel position in a biological product or the stereochemistry of its addition. This often requires extensive chemical or enzymatic manipulation of the biosynthetic product. The complexity of these methods makes them difficult and error prone. Tritium NMR is the simple, rapid, accurate, and nondestructive product analysis technique researchers have sought: an NMR spectrum is acquired as opposed to chemical degradation or analysis. In addition to its relative simplicity, tritium NMR provides more detailed structural and stereochemical information than any other technique.

The group at Surrey University which pioneered ^3H NMR spectroscopy¹ first demonstrated the power of ^3H NMR in biology by following up ^{14}C work on the biosynthesis of penicillin with tritium labeling and tritium NMR. By growing bacteria on media supplemented with tritium-labeled acetate, they were able to determine unambiguously the fate of the methyl protons of acetate in the biosynthesis of the penicillin molecule.² This, and other early work, underscored many of the advantages of using tritium labeling coupled with ^3H NMR analysis. Since 1974 this approach has been applied

Table 1 General Physical and Chemical Data for Tritium, and Common Radioactivity Units^a

Production	${}^6\text{Li}(n, \alpha){}^3\text{H}$
Radiation	β (100%); range = 4.5–6 mm in air, 6 μm in H_2O
β Energy	$E_{\text{max}} = 18.6 \text{ keV}$, $E_{\text{mean}} = 5.7 \text{ keV}$
Half-life	12.43 y (4540 d)
Maximum specific activity	1064 GBq milliatom ⁻¹ (28.76 Ci milliatom ⁻¹)

^a37 gigabecquerels (GBq) = 1 curie (Ci) = 3.7×10^{10} disintegrations per second; 1 gray (Gy) = 10 000 erg g⁻¹ = 100 rad (units of absorbed dose); 1 sievert (Sv) = 100 rem (units of radiation exposure).

Table 2 NMR Properties of ${}^3\text{H}$ and Common NMR Nuclei^a

to much more subtle and complicated problems of enzyme stereochemistry. It has proven especially useful in instances of so-called ‘cryptic’ stereochemistry, where the fate of an individual H atom must be traced, as illustrated in Figure 1(a). Tritium NMR and a fascinating species known as a ‘chiral methyl group’ have emerged as the most powerful method for studying these reactions.

Chiral methyl groups are the smallest chiral entity ever synthesized.³ They are created by attaching each of the isotopes of hydrogen, a proton, deuteron, and triton, to a single carbon atom. If a reaction occurs at this chiral center as in

Figure 1 (a) A chiral methyl group undergoes a substitution reaction: D = deuterium, T = tritium. For a substitution with retention of configuration, the products detectable by ${}^3\text{H}$ NMR spectroscopy are shown in (b) and (c), along with idealized spectra. The effect of a kinetic isotope effect is shown in (d) and (e)

Figure 1(a), ${}^3\text{H}$ NMR analysis of the resulting methylene will give the stereochemical course of the reaction provided that the diastereotopic positions [‘a’ and ‘b’ in Figure 1(a)] are resolvable in the spectrum.

Figure 1(b)–(e) show a breakdown of an ideal substitution reaction to demonstrate how the NMR pattern of products from a chiral methyl reaction may be used to determine enzyme stereospecificity. Reaction of an (S) chiral methyl with retention of configuration is illustrated. Three isotopomeric species can result from the reaction, depending on which isotope of hydrogen is removed. Two of these species contain a tritium atom and may be observed by tritium NMR spectroscopy. One of these products, with a triton at the pro-R position, will give an NMR signal at chemical shift ‘a’, as shown in Figure 1(b). Here the proton was replaced leaving an (R) R-CDT-X species, and the ${}^3\text{H}$ signal is a triplet due to the triton–deuteron coupling (since ${}^2\text{H}$ is spin 1). The chemical shift of this species will also be affected by a deuterium isotope effect. A doublet will also occur in the tritium NMR spectrum from the other product, containing a triton in the pro-S position [at chemical shift ‘b’, Figure 1(c)]. In this species, the deuterium atom was replaced, giving (S) R-CHT-X. If the addition of X had occurred with inversion, the opposite pattern (a doublet at chemical shift ‘a’ and a triplet at ‘b’) would be observed. There is often a primary kinetic isotope effect in the substitution of X, and this will alter the intensity of the lines in the spectrum in a way that also reflects the stereochemistry of the reaction. If configuration is retained and there is a ‘normal’ kinetic isotope effect, the signal at ‘a’ will have a larger integral since it is kinetically more favorable to remove the proton [cf. Figure 1(d) and (e)]. The ratio of the intensities of the lines will directly yield the magnitude of the isotope effect. Thus both the intensity and coupling pattern of the lines in the ${}^3\text{H}$ NMR spectrum are indicative of the stereochemistry of the substitution. If racemization occurs the effect will be obvious, since the mixing of the product species leads to equal intensities at all labeled positions.

Analysis of enzyme stereochemistry using chiral methyl groups is becoming common.^{3–8} Aside from the ability to resolve pro-*R* and pro-*S* chemical shifts, there are other technical requirements. It must be possible to synthesize the chiral tritiated substrate at sufficient specific activity. For probing reactions that are occurring *in vivo* or in cell-free extracts, a high level (5–50 GBq) is usually necessary to ensure sufficient uptake and yield for processing. Biosynthetic yield must also be high enough to provide product in the 4–400 MBq range for NMR analysis. This can be as much as 10⁶-times more radioactivity than commonly used in a simple tracer experiment. In ¹³C, ¹⁵N, and ²H spectroscopy of biomolecules, natural abundance signals may interfere with observation of the added label. In contrast, any tritium signals observed are directly related to the tritium originally introduced as labeled substrate. This feature facilitates the use of tritium NMR for *in vivo* studies, where tritium may be detected in several metabolites, including solvent.⁹

Another crucial and often difficult requirement of this technique is knowledge of the stereochemistry of the methyl group prior to reaction with the enzyme. Currently the most popular method involves the conversion of chiral acetate to acetyl coenzyme A, followed by digestion with malate synthase and fumarase. (This technology is very well described by Floss and Lee,³ which also contains numerous primary references.) The percentage of tritium retention in the fumarase reaction is determined by liquid scintillation counting (LSC), and the enantiomeric excess in the starting acetate can then be calculated. The method depends on the ability to convert the subject chiral methyl group by a sequence of reactions of known stereochemistry into the methyl group of acetate. A more direct approach uses ³H NMR to analyze *N*-methylated 2-methylpiperidine,⁸ where the ability to transfer the chiral methyl species to 2-methylpiperidine builds on much of the same chemistry as the chiral acetate approach. The hindered rotation of the labeled *N*-methyl group makes the chemical shift of the triton dependent on the specific chirality of the methyl carbon. The only disadvantage of this approach compared with the enzymatic determination is the much larger quantities of tritium required for NMR analysis.

2.1 The Berberine Bridge Enzyme

A classic example of the application of chiral methyl groups for understanding cryptic stereochemistry is the study of the berberine bridge enzyme (BBE).⁷ BBE catalyzes the ring-closure reaction shown in Figure 2 to yield scoulerine, which has axial (a) and equatorial (e) methylene hydrogens at the 8-position. These are well resolved ($\Delta\delta = 0.5$ ppm) and their proton chemical shifts are known. The four possible product configurations, ³H_a–¹H_e, ³H_a–²H_e, ³H_e–¹H_a, and ³H_e–²H_a, should all be distinguishable in the ³H NMR spectrum by a combination of their chemical shifts and splitting patterns. Labeled scoulerine was enzymatically synthesized by incubation of *S*-adenosylmethionine with nor-reticuline in the presence of nor-reticuline-*N*-methyltransferase, followed by incubation with BBE. Independent incubations were performed using *S*-adenosylmethionine having exclusively an (*S*)-methyl or (*R*)-methyl, and the ³H NMR spectrum of the purified scoulerine from the (*S*) reaction is reproduced in Figure 3. Spectra were acquired with and without proton decoupling

Figure 2 The biosynthesis of scoulerine by ring closure of a methyl group in reticuline, catalyzed by the berberine bridge enzyme

to help assign tritons coupled to protons, and the deuterium couplings were too small to be resolved at this field [$J(\text{T,D}) = 2.3$ Hz]. The most striking feature of these spectra is the abundance of tritium at the 8-axial position (pro-*R*). This peak is unchanged by proton decoupling, indicating that its geminal partner is a deuterium. The equatorial (pro-*S*) triton is coupled to a proton [$J(\text{T,H}) = 15.3$ Hz]. Since these are the only two tritiated species observed, the berberine bridge enzyme must be acting stereospecifically with exclusive *inversion* during the ring closure reaction. The 4:1 axial to equatorial intensity ratio is explained by a kinetic isotope effect, where $k_{\text{H}}/k_{\text{D}} = 4$.

In this study, 29.6 MBq (800 μCi) of tritium was introduced into the *in vitro* enzymatic system via tritiated *S*-adenosylmethionine, and 5.7 MBq (153 μCi) of scoulerine was purified. One tritium per molecule represents a specific activity of 1064 GBq mmol⁻¹, so 5.7 MBq of scoulerine is 5.3 nmol (ca. 3.2×10^{15} tritiated molecules). At this level of tritium abundance, 24 h of signal averaging (around 50 000 transients) were required to achieve each of the NMR spectra in Figure 3. This is comparable to the length of a standard 2D NMR experiment on a biological sample, and is therefore a small instrumental time commitment relative to the information obtained.

2.2 Cephalosporin C

In the BBE study described above, the amount of radioactivity employed was relatively small since enzymatic reactions were carried out in a cell-free extract. In contrast, studies with a true *in vivo* step may require tritium levels in the multiple curie range. The use of high levels of radioactivity is readily justified in cell systems where the enzymes involved may be unknown or difficult to purify, and elucidation of the biosynthetic route to Cephalosporin C is a good example (Figure 4).⁶ In particular, both the pro-*R* and pro-*S* methyl groups of valine are stereospecifically derivatized in this synthesis, whereby the pro-*S* methyl (*) becomes the exocyclic ester (position 3') and the pro-*R* methyl (II) participates in ring expansion (position 2). The two proton abstractions are catalyzed by different enzymes with very similar properties. Both are 2-oxoglutarate dependent dioxygenases that require Fe(II) and a reducing agent. The stereochemistry of the proton abstractions in these reactions was studied in a very elegant set of experiments using valine molecules with either (*R*)

Figure 3 Tritium NMR spectra of scoulerine. The sample contained 5.7 MBq (153 μ Ci) of tritium in CD_3OD . (a) ^1H gated decoupled, WALTZ-16 ^2H broadband-decoupled, 47 347 transients. (b) Composite pulse broadband ^1H -decoupled, 76 472 transients. (Reprinted with permission from *J. Am. Chem. Soc.*, 1988, **110**, 7878. Copyright 1988 American Chemical Society)

Figure 4 The biosynthesis of Cephalosporin C. The methyl groups of valine are stereospecifically incorporated into the product. This allows analysis of both methyl reactions in the same tritium NMR experiment (see text)

or (*S*) chiral methyl at either the pro-*R* (R) or pro-*S* (S) positions. In this way, both enzyme mechanisms can be studied simultaneously in an *in vivo* synthesis. Each NMR study required ca. 90 GBq (2.5 Ci) of labeled valine substrates added in the cellular media in order to isolate 110 MBq (3 mCi) of cephalosporin (ca. 0.1% yield).

The ^3H NMR spectra of the isolated products are shown in Figure 5, and the combination of starting valine species for

Figure 5 The ^3H NMR spectrum of Cephalosporin C derived from the starting species shown on each figure section. (Reprinted with permission from *Biochem. J.*, 1984, **222**, 777. Copyright 1984 Biochemical Society, London)

each sample is shown on the figure. The signals at 3.2 ppm and 3.4 ppm are the C-2 tritons, and clearly the ring expansion at the 2-position shows little stereochemical preference, since an equal mixture of the possible products is formed. This is consistent with a radical mechanism at this step in the biosynthesis.

The resonances at 4.6 ppm and 4.8 ppm arise from the C-3' tritons, but were not stereospecifically assigned. In contrast to the ring expansion reaction, there is a strong stereochemical preference in reactions at the 3'-position, as shown by the dependence of the 4.8 ppm and 4.6 ppm signal intensities on the configuration of the pro-*S* methyl in the starting valine. The patterns are very similar to those observed in the BBE study described above (see Figure 3), but in this case the minor signal does not represent an *R*-CHT-*X* species since no proton coupling is observed. Since impurities have been ruled out, the remaining possibility is that the enzyme is only about 90% stereospecific, and a 'partial' preference is not uncommon in enzyme-catalyzed reactions.¹⁰ When signals from the *R*-CHT-*X* species are not detected, the isotope effect ($k_{\text{H}}/k_{\text{D}}$) can only be estimated by the size of the spectral noise. In this case, $k_{\text{H}}/k_{\text{D}}$ must be at least 5 for the *R*-CHT-*X* species to be unobservable.

The two similar enzymes studied here have clearly different modes of action in this biosynthetic pathway. The radioactivity and excellent NMR properties of tritium were essential in the synthesis of precursors, isolation of products, and final product analysis in this study.⁶

3 PROTEIN-LIGAND INTERACTIONS

In the study of protein-ligand interactions, the goal is both detailed structural information on binding sites and dynamic information on binding modes and kinetics.¹¹ There

are two major techniques for acquiring detailed structural information on protein structure; X-ray crystallography and NMR spectroscopy. Crystallography can give high-resolution structures but only limited information on dynamics. NMR is an excellent tool for dynamic studies but the size of the system that can be studied is limited, usually by proton resolution, to around 35–40 kDa. Tritium NMR can complement both these approaches. In cases where a crystal- or NMR-derived structural model exists, tritium NMR provides a method for probing dynamics that far exceeds data from crystallography and surpasses NMR with more conventional isotopes in its simplicity and application to larger protein systems. When NMR or crystal structural data are absent, useful information from ^3H chemical shifts, relaxation studies, and ^3H – ^1H NOEs can be used to characterize the ligand binding site.

Here we review two works which are not only exemplary in their demonstration of the power of ^3H NMR in ligand binding investigations, but also show two distinct approaches to the problem which are used repeatedly in the literature.^{12–16} We highly recommend these two studies for those interested in these techniques. The study of maltose binding protein shows how a ligand undergoing exchange at an intermediate rate can be analyzed by standard techniques, e.g. one-dimensional spectra, saturation transfer, and 2D EXSY spectroscopy.¹³ Next we describe how the relaxation behavior of ^3H augmented extensive computer simulation in studying the dynamics of a small inhibitor peptide binding to bacterial collagenase.¹⁴

3.1 Maltose Binding Protein

Maltose binding protein (MBP) is involved in the transport of maltodextrins (maltose and its oligomers) across the periplasmic space in *E. coli*. MBP is a soluble, monomeric protein of 40 kDa, with known primary sequence, which has a dissociation constant for maltose of about 10^{-6} M, increasing somewhat for the longer maltose oligomers. Although there has been a crystal structure determined for MBP, there were questions remaining about the binding kinetics and possible differences in binding of the α and β anomers.

Maltose [Figure 6(d)] and longer maltodextrins were labeled, and tritium was incorporated to a level of 5–20% at the C-1 position. Hence, a limited percentage of ligand molecules were visible to tritium NMR detection. The labeled ligands were characterized by tritium and proton NMR techniques prior to binding studies. The proton-decoupled ^3H NMR spectrum of tritiated maltose in Figure 6(a) is representative of all the oligosaccharides, and shows lines from the α and β anomers at 5.15 ppm and 4.55 ppm (relative to DSS) respectively, with the expected intensity ratio of 40:60.

Initial investigations of the interaction of a labeled ligand and macromolecule invariably involve simple 1D NMR observations of a number of ligand/macromolecule mole ratios. When MBP (ca. 2.5 mM solution, in phosphate buffer at pH 7.0) is titrated with labeled maltose two lines appear, at 3.5 ppm and 3.4 ppm [Figure 6(b), 0.25 equiv.]. The lines are broadened relative to free maltose. This is a common effect in ligand binding studies, which results from the *bound* sugar molecules tumbling with the longer correlation time of the protein. As further additions are made exceeding a 1:1 mole ratio of maltose to MBP, additional peaks due to free maltose are observed at the same chemical shifts as in the absence of protein [Figure 6(b), 2 equiv.].

Very often several deductions can be drawn even from simple 1D ^3H NMR experiments. In this case, the observations are: (a) the large shifts of the bound resonances to lower frequency suggests that the labeled end of the maltose molecule makes direct contact with an aromatic residue in the protein binding site, probably tryptophan 230; (b) the degree of shift of the two anomers is different, which suggests an asymmetric environment around the binding site; and (c) the relative intensity of the bound peaks differs below and above stoichiometric addition. With excess protein, the intensities of the bound forms of the two anomers initially remain at their equilibrium solution value. If the intensities are followed over time, a gradual conversion of the β form into α is observed. When the sugar is present in excess, the *bound* α and *free* β peaks both exceed their equilibrium levels. Both of these observations indicate that there is significant anomeric specificity in binding.

The absolute identity of the bound resonances was determined by saturation transfer and 2D EXSY [Figure 6(c)] techniques, which confirmed that the α anomer is preferentially bound by the protein. These experiments were enhanced by the large chemical shift differences for bound and free sugar resonances, and the saturation transfer studies allowed independent determinations of the dissociation rate constants for α and β anomers. Both the identity of the bound species and the rate constant information is accessible from 2D EXSY experiments, where transfer of magnetization by chemical exchange between bound and free maltose gives rise to the observed cross peaks, and confirms the bound resonance at low frequency as the bound α anomer [Figure 6(c)].

Spectra of longer maltodextrins, containing three to six glucose units, in the presence of excess MBP contained resonances with varying linewidths and average chemical shifts, as a direct result of the range of binding affinities and chemical exchange rates prevalent for the various bound α and β species. Such an array of cases would have been impossible to understand without the simplification conferred by tritium labeling of the ligand and tritium NMR analysis.

In these studies tritium proved to be an excellent direct detection probe with which (a) clear anomeric specificity was observed in a situation where there were few alternative methods for unequivocally demonstrating it, (b) two types of binding (reducing end versus middle or remote) were deduced, this difference being undetectable by other means, and (c) the binding of longer oligomers was characterized with the same or **greater** ease than the maltose case. An added convenience was that the labeling chemistry was straightforward for all the ligands.

3.2 Bacterial Collagenase

As we have mentioned, the other common way to study protein–ligand interactions is by an analysis of the relaxation properties of tritium. An example of using ^3H NMR to study the dynamic and conformational aspects of an inhibitor interaction with bacterial collagenase is the most thorough example of this technique. The protein system was bacterial collagenase from *Achromobacter iophagus* (ca. 71 kDa), and the labeled inhibitor was succinyl-L-prolyl-L-alanine ($K_i = 2.1 \times 10^{-4}$ M), one of a range of competitive inhibitors under study.

Figure 6 (a) $^3\text{H}[^1\text{H}]$ NMR spectrum of $[1-^3\text{H}]$ maltose, (b) the titration of maltose binding protein with tritium-labeled maltose, (c) the 2D EXSY spectrum of excess maltose in the presence of maltose binding protein, (d) the structure of $[1-^3\text{H}]$ maltose

The studies involved rigorous analysis of the relaxation behavior of selected spin systems in labeled inhibitor molecules in the absence and presence of bacterial collagenase. In contrast to the MBP/maltodextrin experiments described above, in this example the experimental data are only the starting point for extensive calculation and interpretation of physical models. Hence sample preparation included rigorous deoxygenation to facilitate accurate relaxation rate measurements, and repetitive determination of these parameters.

The solution behavior of the free ligand was first characterized, before proceeding to inhibition studies. Measurement of the relaxation properties of the tritium pair on the contiguous methylenes in the succinyl residue, and comparison with the relaxation behavior of the complementary protons of the analogously deuterated molecule, allowed the calculation of overall and internal correlation times. From these values, intertritron and interproton distances were estimated, rotamers proposed, and the fractional populations and coupling constants so derived were compared with the experimentally

determined parameters. In these two ways, both the motional (i.e. correlation times) and conformational (rotamer) populations of the free inhibitor were deduced.

Comparable relaxation measurements in the inhibitor/collagenase samples were conducted with a 20–30-fold excess of inhibitor (e.g. 97% free, 3% bound in many experiments), and the spectra showed the weighted average of the NMR parameters of these subspectra, i.e. the chemical shifts and linewidths, etc. We calculate that the tritium samples contained approximately 1000 MBq (27 mCi); [protein] = 40 μ M, therefore [inhibitor] = 1.2 mM, assume 0.5 mL sample (= 0.6 μ mol), specific activity = 45 mCi μ mol⁻¹. By analysis of the cross relaxation of the Ala signals of the proton spectra of the inhibitor/collagenase sample, an indication of the motional freedom of this residue in the presence of protein could be gained, and this indicated that the α -proton had restricted motion. In a similar manner to the free inhibitor, relaxation measurements on the succinyl (Suc) methylenes in the presence of protein permitted the deduction of overall correlation times, internuclear distances, and a qualitative estimate of the order parameter (a measure of the internal mobility of the Suc) for the bound inhibitor. The similarity of tritium and proton cross-relaxation terms for the complementary methylene pairs suggests a similar geometry, and this is satisfied by the carbonyl and carboxy groups adopting a *trans* conformation when bound to the protein.

The natural substrate for this enzyme has the general sequence X–Gly–Pro–Y, and is cleaved at the peptide bond between X and Gly. The studies described above clearly showed that the carboxylate group of the inhibitor Suc residue has the strongest interaction with the enzyme, and that the carbonyl of the Ala residue appeared to be another anchoring site. Using these clues and detailed knowledge of the active site of other zinc proteinases, the structure of the inhibitor may be aligned with that of the natural substrate to identify important structural features. This approach was used to guide the design of improved inhibitors.

4 MACROMOLECULES LABELED WITH TRITIUM

Biological molecules are produced for NMR studies in a variety of ways. The most common are: solid phase synthesis for DNA, peptides, and smaller proteins; in vitro synthesis for RNA production; and in vivo or cellular expression systems, commonly used to prepare ¹³C and ¹⁵N uniformly enriched protein samples. Tritium labeling may be used in conjunction with each of these techniques. The cephalosporin example above demonstrates the in vivo method, while both DNA and RNA have been labeled at several sites demonstrating the use of solid phase and in vitro methods.

The self-complementary DNA dodecamer with sequence 5' dCGCGAATTCGCG 3' has been extensively studied. The proton spectrum is fully assigned and detailed X-ray crystal and NMR structures have been published. Both the crystal structure and recently published NMR data show interesting DNA–water interactions. This molecule has been labeled at the 2- and 8-positions of adenosine-5 (5' dCGCGA*ATTCGCG 3') by addition of a tritiated phosphoramidite precursor at the appropriate step of the solid phase synthesis. Tritium NMR was expected to be helpful in

Figure 7 The 640-MHz tritium-detected ³H–¹H NOESY spectrum of a ³H-labeled DNA oligomer

the further investigation of water interactions since a major difficulty with the proton NMR studies is water suppression.

The one-dimensional spectrum of the tritiated DNA has two lines at 8.1 ppm (8-position) and 7.2 ppm (2-position). Two-dimensional tritium-detected ³H–¹H NOESY spectra of the molecule in H₂O solution showed all the expected intramolecular DNA proton cross peaks, plus cross peaks at the water chemical shift (Figure 7). No water suppression was necessary. In many respects the spectrum in Figure 7 represents a milestone in tritium NMR studies. It is the first and essentially the only heteronuclear ³H–¹H NOESY collected on a macromolecule and fully assigned. Because it directly mirrors the proton spectrum, it demonstrates the fidelity of tritium NMR to proton NMR for the analysis of ‘close in space’ interactions.

The signal at the water chemical shift for both tritons is antiphase, while analogous proton data show purely in-phase cross peaks for this interaction. The major difference between the homo- and heteronuclear spectra is that the water is off-resonance in the tritium-detected experiments. This anomaly is explained by recent observations of multiple quantum interactions between solvent and solute when the solvent is off-resonance (see ‘*Concentrated Solution Effects*’). Although the multiple quantum nature of these cross peaks limits their usefulness in studying DNA–water interactions, their intensity and their acquisition without water suppression indicate that tritium NMR is an excellent method for further investigation of this multiple quantum phenomenon.

RNA has been a particularly difficult molecule to study by NMR methods. The poor dispersion of spectral lines in the ¹H, ¹³C, and ¹⁵N spectra has plagued the structural

Figure 8 A comparison of the aromatic regions of (a) the ^3H (533 MHz) and (b) ^1H (600 MHz) NMR spectra of the 65 base RNA molecule shown in (a)

spectroscopist. Tritium NMR is an effective method for increasing resolution in RNA spectra. Figure 8 compares the ^3H NMR spectrum of a 64-base RNA molecule dissolved in H_2O and the corresponding proton spectrum of an analogous sample dissolved in D_2O (spectral conditions were not identical). The RNA molecule was labeled at the 2-position of each adenosine, giving tritium at 18 of the 75 aromatic sites in the molecule. The spectral simplification afforded by ^3H NMR is actually much more dramatic if it is compared with the proton spectrum in H_2O solution, where dozens of additional exchangeable protons also resonate in the region shown.

With these simpler spectra, it is clear from Figure 8 that the 18 labeled sites on the molecule are not equally represented. Temperature studies confirmed that a significant amount of conformational exchange is occurring in this molecule. Various assignment techniques, including one-dimensional tritium–proton NOE experiments, indicated that the highest degree of conformational exchange is in the central region of the molecule, which includes the bases most important for the self-cleaving properties of this RNA molecule. This conformational exchange is totally undetectable in the proton spectrum and would be difficult to analyze by a technique other than tritium NMR.

The DNA and RNA samples were labeled at high specific activity. The DNA was approximately $1500 \text{ GBq mmol}^{-1}$ (40 Ci mmol^{-1}) at two sites and the RNA was more than $15\,000 \text{ GBq mmol}^{-1}$ (400 Ci mmol^{-1}) at 18 sites. These high levels of activity are beneficial for the rapid acquisition of

spectra, but also accelerate radiation decomposition of the substrates. As a result, the samples discussed here had a useful lifetime of only 3 to 5 weeks. In cases where samples are concentration limited, high specific activity is the only alternative and a short sample lifetime should be expected. If the working concentration is not strictly limited by the properties of the sample, it is better to label at lower abundance and store the sample in dilute form, concentrating it only for NMR experiments. DNA and RNA labeling with tritium requires about the same amount of effort as the more common ^{13}C and ^{15}N techniques. In contrast to these nuclei, tritium is much more sensitive and can be directly detected without the need for water suppression.

5 CONCLUSION

The NMR properties of tritium are slightly better than those of ^1H , with essentially zero natural abundance. Hence it is possible to detect tritium with more sensitivity than the hydrogen it replaces, and spectral simplification is assured. Radioactivity is the only issue hindering the universal application of tritium in biological NMR studies.

1 INTRODUCTION

1.1 Notation and Definition

An excitation sequence is made up of one or more pulses. It may be organized in subsequences of pulses. A selective pulse, subsequence, or sequence is one that excites spins in only a fraction of the spectral region of interest. Examples are a soft pulse and a DANTE subsequence. The prefix ‘sub’ may be omitted.

The term *saturation* is used to describe not only a state in which the longitudinal magnetization is zero throughout the sample, but any condition (e.g., that produced by forced nutation) that is operationally equivalent to uniform zero longitudinal magnetization.

1.2 Solvent Signal Suppression

It is often necessary to obtain proton NMR spectra of compounds whose concentration is in the millimolar range, dissolved in protonated solvents, such as H₂O rather than D₂O. This is the case for NMR of exchangeable protons, or in proton NMR in vivo. With nonselective pulse excitation, the high concentration of water protons, about 110 M, raises serious difficulties, such as saturation of the analog receiver or of the analog-to-digital converter, resulting in artifacts that could render the spectrum useless. It is therefore necessary to reduce the solvent signal.¹

There are two stages in solvent signal suppression (SSS). The first is the reduction of the solvent contribution to the signal generated by the NMR probe, so as to prevent receiver saturation. This stage cannot be dispensed with. Methods for its implementation are of two types: those that perturb the solvent magnetization (e.g., by saturation), and those that leave it unchanged. The latter are preferred, or even indispensable, for the study of exchangeable protons.

The second stage consists in data postprocessing with the aim of further reduction of the residual solvent signal.

Suppression of the signal of the solvent, but not of the signals of the solutes, must use some difference between these. The most general difference is in the chemical shift, and most of this article is indeed devoted to SSS methods based on frequency differences between solvent and solutes.

However, any property distinguishing solvent from solute may be, and usually has been, recruited to aid in SSS. In the case of water, this includes

1. the small size of the molecule, leading to
 - (a) fast rotational Brownian motion and hence long T_1 ,
 - (b) fast translational Brownian motion and hence fast diffusion;
2. the equivalence of the two protons and consequent absence of J splitting;
3. the (obvious) lack of heteronuclear couplings to nitrogen or carbon.

An ideal SSS method would be universal, would suppress the solvent signal, and would leave all others unchanged. It would also be easy to implement, and would not be too demanding on the specifications of the spectrometer. In practice, the varieties of experimental situations and spectrometer limitations result in a large number of diverse cases, with different criteria for solvent suppression. Therefore, no SSS method is best for all cases at present. Despite this caveat, we shall risk general guidelines that apply to both 1D and n D NMR.

The first stage of SSS should reduce the solvent signal as required to avoid saturation of the receiver while keeping as small as possible any perturbations of the properties observable in the NMR spectrum, such as chemical exchange, NOE, signal-to-noise ratio and spectral (phase) distortions. Among frequency-selective SSS excitation sequences, the JR sequences described in Section 3.2.5 may be recommended on this basis.

All further reductions of the solvent signal should be left to data postprocessing. We recommend data processing in the frequency domain, including

1. the automatic subtraction of Lorentzians centered in a narrow window centered at the solvent frequency;
2. the automatic correction of spectral amplitude as required by the frequency-selective excitation procedure.

An elementary criterion for the quality of the SSS procedure is that NO linear phase correction or baseline correction should be needed, beyond those used on the same spectrometer in the case of excitation with a single 90° pulse.

1.3 A Single Long Pulse

In order to avoid excessive abstraction, we now describe a method of solvent signal suppression. It uses a single excitation pulse at the frequency of the spins of interest, such that they rotate by an angle θ away from Oz , whereas the solvent spins end up along Oz after the pulse.

A good description of the single long pulse method can be made in a *rotating frame*—one that rotates around the z axis at the excitation frequency (Figure 1a). In this frame, the excitation field $\mathbf{b}_1$ is static, and this is the effective field for a spin whose resonance frequency is equal to the excitation frequency. The effective field $\mathbf{b}_{\text{eff}}$ for the solvent spins, offset by $\omega/2\pi$ from the excitation frequency, has, besides the transverse component $\mathbf{b}_1$, a longitudinal component $(-\omega/\gamma)\mathbf{k}$,

where γ is the gyromagnetic ratio and $\mathbf{k}$ is the unit vector along the z axis. Each spin rotates around its effective field, at an angular frequency $\omega_{\text{eff}} = -\gamma|\mathbf{b}_{\text{eff}}|$.

At the end of a pulse lasting τ , the spins have rotated respectively by

$$\theta_{\text{resonant}} = -\gamma b_1 \tau \quad (1)$$

$$\theta_{\text{nonresonant}} = -\gamma \left[b_1^2 + \left(\frac{\omega}{\gamma} \right)^2 \right]^{1/2} \tau \quad (2)$$

Solvent signal suppression is obtained if $\theta_{\text{nonresonant}} = 2\pi$. Together with a choice of θ_{resonant} , this specifies the amplitude b_1 and duration τ of the pulse:

$$\tau = \frac{(4\pi^2 - \theta_{\text{resonant}}^2)^{1/2}}{|\omega|} \quad (3)$$

Equation (3) shows that the length of the pulse is a function of the frequency difference ω between the spins to be seen and those to be suppressed. More generally, for a strong variation of the excitation spectrum within a range ω_s , pulse lengths or intervals in the range of $2\pi/\omega_s$ are required. At 400 MHz, for a difference in chemical shift of 8 ppm, this corresponds to $\tau = 312 \mu\text{s}$. To satisfy equation (1), a pulse of this length must be weak—or ‘soft’, as is commonly said.

The amplitude and phase of the transverse magnetization created by the soft pulse are shown in Figure 1(b) as functions of the frequency offset. The transverse magnetization is indeed zero at the solvent frequency, and maximum for the resonant spins. The phase of the transverse magnetization is approximately proportional to the frequency offset—the so-called linear phase shift.

This method has two qualities:

1. it is simple, and demands little of the spectrometer in terms of phase or amplitude modulation of the excitation pulse;
2. it restores the solvent magnetization to its original orientation.

It has two drawbacks:

1. the frequency of the excitation zero depends on the rf field amplitude [equation (2)], so that the degree of solvent signal suppression is susceptible to equipment drift;
2. compensation of the linear phase shift generates baseline distortions.

These features are important for SSS, and they will be considered anew as we examine principles and implementations of SSS.

1.4 Scope of This Article

Solvent signal suppression was originally developed in the framework of 1D NMR applications to chemistry and biochemistry. Nowadays, these applications often involve 2D and 3D NMR. SSS is also used in *in vivo* localized proton NMR spectroscopy, in which the rf field may be strongly inhomogeneous, and the water peak may have contributions not only from the volume of interest but also from large surrounding regions.

The emphasis of this article is on SSS fundamentals, which, despite differences in methodology, are the same in the three domains. Furthermore, the similarity in hardware and software

Figure 1 (a) The motion of the magnetic moment in the presence of a weak rotating field $\mathbf{b}_1$, as viewed in the frame rotating at the frequency of the field, aligned along Ox . The effective field $\mathbf{b}_{\text{eff}}$ is represented. Its components are $(-\omega/\gamma)\mathbf{k}$ and $\mathbf{b}_1$. The small circle is the trajectory of the magnetic moment, whose initial position is along the z axis. The scale is such that the lengths of the magnetic moment and of the effective field are equal. (b) Amplitude and phase of the transverse magnetic moment after a $\frac{1}{2}\pi$ pulse lasting τ , as a function of the frequency offset ν . The signal at $\nu = (\frac{15}{16})^{1/2}/\tau$ is suppressed (single long pulse technique). (Modified from M. Guéron, P. Plateau, and M. Decors, in ‘Progress in Nuclear Magnetic Resonance Spectroscopy’, eds. J. W. Emsley, J. Feeney, and L. H. Sutcliffe, Pergamon Press, Oxford, 1991, Vol. 23, p. 138, Copyright 1991, with permission from Pergamon Press Ltd)

leads to comparable limitations on SSS. The discussion is mostly in terms of 1D NMR, and specific problems of 2D and 3D NMR are treated in a separate section. See also *Water Suppression in Proton MRS of Humans and Animals*.

The question of SSS also arises in the context of subtractive techniques, as used for instance in homo- or heteronuclear editing techniques like reverse INEPT, or multiquantum NMR. The subtractive character may help considerably with respect to SSS. This is mostly outside the scope of the present article, as are tailored excitation,² the use of notch filters,³ rapid scan FT NMR,⁴ and stochastic excitation.⁵

The reader in need of more information on SSS is referred to the extensive original literature, to recent reviews,^{6,7} and to related articles in this Encyclopedia.

2 WHY SUPPRESS THE SOLVENT SIGNAL?

Solvent signal suppression is required because it is impossible to acquire the free induction decay of the large solvent signal while maintaining maximum sensitivity for other signals.

2.1 Acquisition of the Free Precession

For good sensitivity, the noise issuing from the probe should be amplified to a value no less than one least significant bit of the analog-to-digital converter (ADC). Signals that are buried in the noise can then be recovered without loss in signal-to-noise ratio (S/N). The RMS thermal noise of a resistor r in a bandwidth $\Delta\nu$, $(4rk_B T \Delta\nu)^{1/2}$, is $0.09 \mu\text{V}$ for 50Ω and 10 kHz , and the appropriate receiver gain is then about 10^4 if the least significant bit of the ADC is 1 mV .

The maximum value of the FID must remain within the range of the ADC. It must therefore be less than 4096 times the noise for a 12-bit ADC, and 65 536 times for a 16-bit ADC. Since the noise increases with the bandwidth, the S/N of the FID, and together with it the required dynamic range of the receiver, may be reduced by increasing the bandwidth,⁸ at no cost in the S/N of the spectrum.

The ratio of mean square signal to mean square noise (S/N)² at the beginning of the free precession following a $\frac{1}{2}\pi$ pulse is given by⁷

$$(S/N)^2 = \frac{mB_0/t_R}{4Fk_B T \Delta\nu} \quad (4)$$

where m is the magnetic moment within the probe, B_0 is the static field, and F is the noise factor of the receiver; t_R is the time for radiation damping⁹ of a parallel-tuned circuit, given in SI units by

$$t_R^{-1} = \frac{M\gamma\eta Q}{2\epsilon_0 c^2} \quad (5)$$

Here, $4\pi\epsilon_0 c^2 = 10^7$, M is the magnetization (the magnetic moment per unit volume), Q is the quality factor of the tuned circuit, and η is the filling factor. For water protons, M at equilibrium in a field B at room temperature is equal to $3.24 \times 10^{-3} B$, and $t_R^{-1} = 168\eta Q M$.

According to equation (4), the volt ratio (S/N $\times 2\sqrt{2}$) of the peak-to-peak signal from $200 \mu\text{L}$ H_2O at 400 MHz to the RMS

noise in a bandwidth of 10 kHz is about 3.8×10^5 , or $2^{18.5}$, assuming that $Q\eta = 10$. Proper acquisition of the FID would thus require a 19-bit ADC together with a receiver having the same dynamic range. If a 12-bit ADC is used, the excitation procedure must reduce the water signal by a factor of at least 2^7 , i.e., 128.

Note that the S/N of the FID is not equal to that of the spectrum. Indeed, the maximum value of the FID, right after a $\frac{1}{2}\pi$ pulse, corresponds to the integral of the spectrum, and is therefore independent of the linewidth, whereas the signal height in the spectrum is inversely proportional to it.

After attenuation by a factor of 128, sufficient for signal acquisition, the remaining water signal is still huge, but it may be reduced by postacquisition processing. Acquisition methods that provide a larger SSS factor than strictly required by the constraint of dynamic range are convenient, because they are more tolerant of spectrometer imperfections and may require less postacquisition processing. However, they have some problems. Typically, they use second- or third-order suppression, which creates a large region near the solvent frequency where the magnetic signals, but not the thermal noise of the probe, are reduced. The longer excitation sequence may affect measurements requiring multiple, closely spaced excitation pulses (spin echoes, inversion–recovery, 2D NMR, localized spectroscopy). It may also create spurious effects of cross polarization (NOE) and chemical exchange. Postacquisition processing suffers from none of these defects, and is therefore preferable in principle.

2.2 The ‘Rolling Baseline’

Let us go back to the single long pulse described in Section 1. At the end of the pulse, the water magnetization is returned to the z axis, there is no transverse magnetization, and the amplitude of the water signal is zero.

Consider now a Bloch spin with central frequency ω_C close to, but distinct from that of the solvent. At the end of the excitation pulse, its magnetization will have a small transverse component. This will generate a FID, which will, as usual, decay exponentially according to T_2 , and whose Fourier transform will therefore be the customary Lorentzian, or, in other words, the Bloch lineshape. The point is that this Lorentzian will have a finite, nonzero amplitude at the frequency of the solvent, that is, at the frequency of null excitation!

This shows that the solvent suppression scheme does not, strictly speaking, generate a frequency-dependent attenuation.⁷ Rather, *it attenuates without distortion each Lorentzian line as a function of its central frequency: the suppression procedure acts on the entire Lorentzian*. In the same way, each Lorentzian is phase-shifted by a *constant* phase angle that is only a function of the central frequency.

This is not the same thing as a frequency-dependent phase shift,¹ and it cannot therefore be corrected by a true frequency-dependent phase shift of opposite value. Such a correction does not conserve Lorentzians, and this gives rise to the ‘rolling baseline’ defect that appears in Figure 2. This defect could be avoided by more sophisticated correction procedures.⁷ Even better would be excitation procedures that do not produce a linear phase shift.

Figure 2 Simulated spectra of two Lorentzian lines (from species i and j), having the same width (5 Hz), and whose intensities are in the ratio of 1:100. The frequency separation is 2500 Hz. Only the absorption is shown. (a) The Fourier transform of the response to a hard pulse is the true spectrum, $S(\omega) = S_i(\omega) + S_j(\omega)$. (b) The Fourier transform $E(\omega)$ of the same response, except that acquisition begins $400\ \mu\text{s}$ after the hard pulse. It is the sum of the two Lorentzians, with their phases offset by $\frac{1}{2}\pi$. The constant phase is chosen so that line i is phased in absorption. (c) The spectrum $D(\omega)$ that results from the application of a linear phase correction to $E(\omega)$, chosen so that each line is properly phased near its center. Since the phase varies with frequency, each line is distorted to a non-Lorentzian shape. The 'baseline roll' comes from the dispersion wing of the intense j line. (Reproduced from M. Guéron, P. Plateau, and M. Decors, in 'Progress in Nuclear Magnetic Resonance Spectroscopy', eds. J. W. Emsley, J. Feeney, and L. H. Sutcliffe, Pergamon Press, Oxford, 1991, Vol. 23, p. 151, Copyright 1991, with permission from Pergamon Press Ltd)

3 EXCITATION SCHEMES FOR SSS

The number and variety of SSS methods may seem overwhelming, with new ones being published monthly. One may nevertheless attempt to clarify the situation, as follows.

1. Many methods are useful only in particular conditions.

2. Interesting new methods are usually those that take advantage of the new possibilities of modern spectrometers, in particular fast and flexible control of rf phase and amplitude, and, most importantly, the generation of pulsed gradients.
3. Methods with modest hardware requirements are accessible to more users, and they are less susceptible to hardware imperfections. This argues in favor of symmetric sequences, which help to compensate spectrometer imperfections; short sequences, which minimize spurious evolutions (e.g., radiation damping and magnetization transfer) during the sequence; and strong pulses.
4. The linear phase shift is a source of distortions that are only corrected with difficulty: it can and should be avoided.
5. Many SSS excitation methods lead to saturation of the solvent resonance, and this may change the magnetization of some solute protons (e.g., imino protons of nucleic acids) by way of NOE or chemical exchange. Methods that leave the solvent magnetization at equilibrium do not produce such side effects. They are therefore more generally applicable.

In this section, we present a selection of SSS methods that provide examples of the characteristics just described. They are separated into two classes: those that alter the solvent magnetization and those that do not.

3.1 Methods That Alter the Solvent Magnetization

SSS may be obtained by canceling the solvent magnetization. Solvent/solute discrimination may be based on a difference in the chemical shift, or in the rates of longitudinal or transverse relaxation or even of diffusion. Methods based on relaxation require a time in the range of T_1 or T_2 . Methods based on the inhomogeneity of the main field B_0 or of the rf field b_1 may operate much faster. The required time is in the range of $(\gamma\delta)^{-1}$, where δ is the variation of the field over the sample.

Let us start with relaxation-based methods. In method (a) (Figure 3), the solvent magnetization is selectively saturated by a long and weak pulse at the solvent resonance frequency, after which the strong observation pulse is applied. In method (b), the solvent magnetization is selectively inverted by a weak pulse or by a series of intense pulses, the so-called DANTE sequence,¹⁰ and residual transverse magnetization is destroyed with a gradient pulse. The observation pulse is applied when the longitudinal magnetization becomes null, after a time T_1 in 2, where T_1 is the longitudinal relaxation time of the solvent. Method (c) (WEFT)^{11,12} is a variant of (b). It is simple to set up in that it uses only strong, nonselective pulses. Because all spins are inverted by the first pulse, it works only if the *longitudinal* relaxation of the solvent is slower than that of the protons of interest. This will often be the case, because of the relatively small size of the water molecule, which results in a large *rotational* diffusion coefficient.

When the *transverse* relaxation of the solvent is faster than that of the spins of interest, one can achieve SSS by the WATR method.¹³ This is a spin echo method, in which the refocusing π pulse occurs after a time much longer than the transverse relaxation time of water protons, which are therefore not refocused. Relaxation may be enhanced by paramagnetic ions,¹⁴ or by proton exchange with ammonia or urea.¹⁵ The

Figure 3 Four SSS sequences, based on saturation of the solvent signal. In methods (a) and (b), discrimination between solvent and solutes is achieved by frequency-selective excitation. In method (c), the water proton is selected by its long longitudinal relaxation time. Method (d), in contrast to (a)–(c), produces saturation quickly, independently of relaxation. (Modified from M. Guéron, P. Plateau, and M. Decors, in ‘Progress in Nuclear Magnetic Resonance Spectroscopy’, eds. J. W. Emsley, J. Feeney, and L. H. Sutcliffe, Pergamon Press, Oxford, 1991, Vol. 23, p. 154, Copyright 1991, with permission from Pergamon Press Ltd)

method is also applied to the elimination of the signal from water or fat in biological tissues. Both WEFT and WATR have a flat spectral response, including at the solvent frequency.

Spurious effects of solvent saturation are reduced in methods that achieve solvent saturation quickly, independently of relaxation. In method (d) of Figure 3, a selective $\frac{1}{2}\pi$ pulse is followed by a gradient pulse (‘homospoil’), which destroys the transverse magnetization.¹⁶ With forced nutation¹⁷ in an inhomogeneous rf field $b_1 \pm \delta b_1$, saturation is obtained in a time $(\gamma \delta b_1)^{-1}$. Forced nutation of the solvent spins may be combined with *spin locking* of the solute spins, so that all signals, including the solvent residual, end up in-phase. The method applies to 1D and 2D NMR and to *in vivo* spectroscopy.^{18–21} This is also the case for the ‘WATERGATE’ (water-suppression by gradient-tailored excitation) method when the observed signal is a spin echo, from which the water proton signal is absent because the refocusing π pulse is selective.²²

In the ‘DRYCLEAN’ method,²³ one uses the large *translational* diffusion coefficient of water as compared with macromolecules: the transverse water magnetization is selectively destroyed by the application of a pulsed magnetic field gradient during a spin echo sequence.²⁴ A beautiful extension of this concept has been made in the case of proton NMR of perfused cells,²⁵ for which SSS is particularly important, since the cells occupy only a small fraction (about 1%) of the total

volume. Furthermore, the signals of the extracellular solutes must also be suppressed. The diffusion method discriminates between intra- and extracellular products, because the range of diffusion of the latter is restricted by the cell membrane. For an appropriate duration of the gradient pulse, signals from extracellular water and solute are suppressed, while the intracellular ones are unaffected by diffusion. The signal of the intramolecular water is suppressed by other characteristics of the excitation sequence, such as frequency selectivity.

3.2 Methods That Avoid Solvent Saturation

3.2.1 Long Pulses

A weak or long or selective pulse is one for which b_1 is smaller than the chemical shift range of the spectrum, so that the pulse acts differently on different spin species. These differences are used in the ‘long pulse’ suppression methods, such as the ‘single long pulse’ described in Section 1.

The excitation spectrum of a long pulse may be usefully modified by modulating its phase, as in Redfield’s ‘214’ pulse,¹ whose time sequence is 2142, the underlined numbers corresponding to times during which the phase is shifted by π . Its excitation spectrum has two closely spaced zeros. Similar sequences have a second-order zero.⁷ This protects against instrumental imperfections, such as inhomogeneity or drift in field or in temperature, all of which generate water signals at frequencies differing slightly from the nominal excitation zero. The sequence is also less sensitive to rf field inhomogeneity. The cost is reduced sensitivity close to the solvent frequency.

3.2.2 Short Pulses; Binomial Sequences

Binomial sequences consist of sequences of pulses whose amplitudes are proportional to the binomial coefficients, separated by equal interpulse delays. The simplest binomial sequence is 1, 1 (two pulses of equal amplitude and phase, separated by a delay), at the frequency of maximum signal. An exact, as opposed to linear, description may be given in the rotating frame. The first pulse tilts the spins by, for instance, $\frac{1}{6}\pi$ in the direction of the y axis. During the delay, the solvent spins rotate by $\omega\tau = \pi$ and the spins to be observed are immobile. The second and last pulse, at time 0, brings the water protons back along Oz , while the spins to be observed end up tilted by $\frac{1}{3}\pi$ towards the y axis (Figure 4). Spins with intermediate chemical shifts are less tilted, and their transverse components have different directions, corresponding to a frequency-dependent phase shift.

The excitation may be described as two delta functions of opposite sign, at times $-\tau$ and 0. In the linear approximation, the spin response is determined by the Fourier transform of this sequence (the excitation spectrum), which is simply $e^{-i\omega\tau} + 1$, or $2e^{-i\omega\tau/2} \cos \frac{1}{2}\omega\tau$. The latter expression displays the frequency dependence of amplitude and phase. The amplitude is maximum for $\omega\tau = 0$, and zero for $\omega\tau = \pi$. The phase varies linearly from 0 to $\frac{1}{2}\pi$ in this frequency range.

This sequence has the following properties.

1. The evolution of the spins is easily described, because the excitation is a combination of hard pulses during which all spins rotate around the same pulse axis, and of waiting periods during which all spins rotate around the same Oz axis.

Figure 4 The simplest binomial SSS sequence: 1, 1. The gray line represents the motion of the solvent magnetization, ending in the Oz direction; the black line represents the motion of the magnetization of the resonant spins. (Modified from M. Guéron, P. Plateau, and M. Decors, in 'Progress in Nuclear Magnetic Resonance Spectroscopy', eds. J. W. Emsley, J. Feeney, and L. H. Sutcliffe, Pergamon Press, Oxford, 1991, Vol. 23, p. 157, Copyright 1991, with permission from Pergamon Press Ltd)

2. Hard pulses provide excitation over a large spectral region.
3. Owing to the symmetry of the sequence, spatial inhomogeneity or long-term drift of the pulse amplitude does not change the frequency of the excitation zero.

In the linear approximation, a binomial sequence of order n provides suppression to the same order. The 1, -2 , 1 (i.e., 1, -1 , immediately followed by -1 , 1) and 1, 2, 1 excitation sequences provide second-order suppression for all pulse angles.

The main drawback of the binomial sequences is the linear phase shift of the excitation spectrum. It is considerably reduced, without change of the amplitude response, in a *modified binomial sequence*, which consists of a binomial inserted between a $-\pi$ and a $+\pi$ pulse.^{7,26,27} More complex hard pulse SSS sequences can be built on the basis of extensive computer searches.^{28,29}

3.2.3 Combinations of Selective and Nonselective Subsequences

As an example, consider a sequence consisting of a soft pulse of angle θ , followed by a hard pulse of angle $-\theta$, both at the solvent frequency.¹¹ The response to the soft pulse has strong phase shifts, but it is limited to a narrow range around the solvent frequency. The subsequent hard pulse provides nonselective excitation without phase shift, and cancels the effect of the soft pulse on the solvent magnetization. This sequence therefore provides a nearly flat and phased response. In this way, the two functions of the excitation sequence, signal suppression in a narrow range and observation in a broad range, are well separated. On the other hand, the inherent

asymmetry of the method makes it sensitive to hardware imperfections.

3.2.4 Echoes, Gradients and EXORCYCLE

The linear phase may be avoided by generation of a spin echo. An echo excitation sequence consists of two parts: the excitation subsequence E1, which generates transverse magnetization, and a refocusing subsequence E2. E1 and/or E2 may be designed to provide SSS.

If E1 is a selective binomial, it produces a linear phase shift whose sign corresponds to a *delay*. This is changed to one corresponding to an *advance* in the echo. The latter is easily compensated by waiting for an equal time following the echo center time, prior to the acquisition. Another procedure is to acquire the complete echo. Its Fourier transform has an imaginary component, but nevertheless it has no contribution from the dispersion of any spin signal, so that a frequency-dependent phase correction will not produce much baseline roll. The properties of complete echoes have been applied to magnetic resonance imaging and 2D NMR, and recently to in vivo proton spectroscopy.³⁰ They can also be used for phase correction of the free precession itself, as in the 'pseudoecho' method.^{28,31} The order of the zero in the spectral response to an echo sequence may be uncomfortably high. For instance if E1 and E2 have a first-order zero at the solvent frequency, the zero of the echo response is third order.

An echo may be generated by a 90° pulse for E1 and a 180° pulse for E2. With other subsequences, spurious free precession contributions combine with the echo. Such deviations occur when the rf field is inhomogeneous, for instance in in vivo spectroscopy with surface coils, and with frequency-selective excitation for SSS. To obtain a pure echo under such conditions, one may use sequences in which the transverse magnetization is suppressed at appropriate times with a pulsed gradient. Or one may add successive acquisitions in which the excitation phases are shifted according to the EXORCYCLE scheme.^{7,32}

3.2.5 Jump and Return (JR)

The 'jump and return' (JR) excitation sequence includes two $\frac{1}{2}\pi$ pulses of opposite phases, at the solvent frequency.³³ The first pulse brings all spins along Oy in the rotating frame (Figure 5). During the interval between the pulses, the water protons remain along Oy and the spins of interest precess by $\frac{1}{2}\pi$ in the equatorial xOy plane. The second pulse rotates the xOy plane into the vertical xOz plane, so that all spin species end up with their transverse component along $\pm Ox$. Hence, the phase is constant across the spectrum, except for a step of π at the solvent frequency (Figure 6a). The solvent magnetization ends up along Oz , providing first-order SSS. Spins for which $\omega\tau = \frac{1}{2}\pi$ end up along Ox , corresponding to maximum signal.

The three successive rotations of the magnetization that are produced by JR have the same effect as a single rotation of angle $\omega\tau$ around Oy . This result is valid whatever the original orientation of the magnetization. For instance, two successive JR excitations rotate the ($\omega\tau = \frac{1}{2}\pi$) spins by π while preserving SSS.

The most interesting property of JR is the *lack of linear phase shift*, a property that obtains only for a specific pulse angle, $\frac{1}{2}\pi$ (or multiples), in the case of a very large b_1 field. If

Figure 5 The ‘jump and return’ sequence. With the first $\frac{1}{2}\pi$ pulse, all spins jump to the Oy direction. During the waiting time τ , they rotate in the (x,y) plane by $\omega\tau$, ω being their frequency offset from the pulse frequency, which is the resonance frequency of the solvent. The second pulse, $-\frac{1}{2}\pi$, brings all spins in the (z,x) plane; hence, their transverse magnetizations are all along $\pm Ox$, so that there is no linear phase shift. The solvent spins return to the starting position along Oz . The effect of JR on each spin is a rotation by $\omega\tau$ around Oy . (Reproduced from M. Guéron, P. Plateau, and M. Decorps, in ‘Progress in Nuclear Magnetic Resonance Spectroscopy’, eds. J. W. Emsley, J. Feeney, and L. H. Sutcliffe, Pergamon Press, Oxford, 1991, Vol. 23, p. 160, Copyright 1991, with permission from Pergamon Press Ltd)

the angle differs slightly from this value, there will be a slight linear phase shift. But the SSS feature will not be affected. This makes the JR sequence robust with respect to spectrometer instability.

JR is the shortest known SSS sequence, being twice as short as the shortest binomial sequence, 1, -1 : with JR, the spins of interest precess by $\frac{1}{2}\pi$ during the waiting period, whereas with 1, -1 , the precession angle is π (Figure 4).

For spins whose frequency is close to that of maximum sensitivity, the rotation angle is close to $\frac{1}{2}\pi$. Thus, one can create an SSS version of any multipulse sequence of $\frac{1}{2}\pi$ pulses (or multiples) by simply replacing each pulse by a JR sequence. Application to 2D NMR is discussed in Section 6.

If the pulse angle is larger than $\frac{1}{2}\pi$, the JR sequence produces a phase shift corresponding to a negative delay, leading to a *spin echo*.²⁷

The JR sequence is simple to adjust. The residual water signal should be observed on the free precession, whose phase and quadrature components should be available for display. The adjustment process is preferably carried out by analog controls in real time, rather than by computer-controlled procedures, whose response may be inconveniently slow. The Ox component is canceled by adjusting either the excitation frequency or the phase of one of the pulses. The Oy component is canceled by adjusting the length of one pulse. In this way, one corrects for hardware errors, as well as for movements of the water proton magnetization in the rotating frame due to frequency maladjustment, longitudinal relaxation, and radiation damping. JR has intrinsic compensation for transverse relaxation.

JR can be adapted to excitation frequencies distinct from the solvent frequency.

When the b_1 field is not very large, the JR response presents a quasilinear phase shift, and the frequency of maximum response is modified. These effects are avoided with the *power-adapted JR* (PJR) procedure,²⁷ whose frequency response is very close in phase and amplitude to that of JR with infinitely strong pulses. Let t_p be the length of a $\frac{1}{2}\pi$ pulse and let τ , as

before, be equal to $\pi/2\omega_{\max}$. Define a power parameter p by

$$p = t_p/\tau \quad (6)$$

In power-adapted JR, the pulse length is

$$t'_p = \frac{t_p}{1 - (2/\pi)p} \quad (7)$$

and the interval τ' between the beginnings of the pulses is

$$\tau' = \tau(1 - \frac{1}{3}p) \quad (8)$$

The JR sequence shares with the 1, -1 sequence a linear amplitude response for Larmor frequencies close to that of the solvent. This is a blessing, since it enables one to observe signals close to the solvent. Although solvent suppression is not as good as with higher-order sequences, this may be corrected after the acquisition. Alternatively, one may use SJR, a second-order modification of JR.³³

4 EXPERIMENTAL ASPECTS

SSS is affected by instrumental imperfections of the excitation sequence, by relaxation and radiation damping during excitation, and by inhomogeneities in the static and rf fields. The practical analysis and adjustment of an SSS sequence require observation of the free induction decay in real time on an oscilloscope. A discussion of these matters may be found in Guéron et al.⁷ Only a brief survey is given here.

Relaxation and radiation damping affect SSS by reorienting the magnetic moment of solvent spins during the excitation period. Radiation damping is the most significant, because its rate is usually the largest and because it may be inhomogeneous in the sample. Some SSS sequences (e.g., the binomial 1, -2 , 1) automatically provide first-order compensation of radiation damping.

Figure 6 Proposed standard test for SSS. (a) JR spectrum of thymidine, 10 mM, in 90% H₂O, 10% D₂O. A single FID was collected. The length of a $\frac{1}{2}\pi$ pulse was 10 μ s. The frequency of maximum sensitivity is at 11.1 ppm. No phase correction was applied, except for that used in the case of single pulse excitation. The imino proton signal (11.1 ppm) is broadened by exchange. Exponential multiplication provides 3 Hz broadening and insures that the peak heights are not sensitive to field inhomogeneity. By comparison with the H-5 signal at 7.7 ppm [spectra (a)–(d)], the suppression factor is about 1000. Proton frequency, 360 MHz; 5 mm outer-diameter sample tube; $T = 20^\circ\text{C}$, pH 4. Acquisition and data processing were performed with networked 80386 PC-type computers, running MS-DOS, with 20 MHz clock. (b) Spectrum derived from (a) by repeated subtraction (10 times) of a Lorentzian simulating the tallest peak within ± 75 Hz of water (dotted lines). Total processing time 4 s. (c) Spectrum derived from (b) by correction of the JR amplitude response. The correction, which is not applied to the range within ± 95 Hz of water (dotted lines), does not change the signal-to-noise ratio. (d) Spectrum of thymidine, 10 mM, in D₂O, following a single $\frac{1}{2}\pi$ pulse. Other conditions are as in (a). This spectrum is provided as a reference for evaluation of spectrum (c), which is the result of JR excitation and processing. In spectrum (c), (i) the maximum sensitivity is the same as in (d), (ii) relative signal amplitudes are respected, and (iii) the H-3' signal at 4.45 ppm demonstrates good observability and lack of artifacts near the water position (4.82 ppm). Spectrum (c) was obtained from the FID in about 6 s processing time. (Reproduced from M. Guéron, P. Plateau, and M. Decors, in 'Progress in Nuclear Magnetic Resonance Spectroscopy', eds. J. W. Emsley, J. Feeney, and L. H. Sutcliffe, Pergamon Press, Oxford, 1991, Vol. 23, p. 135, Copyright 1991, with permission from Pergamon Press Ltd)

Static field inhomogeneities also affects SSS, particularly those such as Z^2 that give asymmetric lineshapes. It may also happen that small fractions of the sample suffer from large field offsets—either because they are rather far from the center of the sample or because of diamagnetic susceptibility anomalies. Examples are isolated drops on the sample tube wall, and the

sample region located at the bottom of the sample tube. If they amount to 1% of the sample volume, they may limit the SSS factor to a few hundred. Even worse, they may generate artifactual lines in the spectrum. Appropriate probe designs help to reduce these problems. Sample tubes with a flat bottom and a long tail are recommended.⁷

4.1 Spectrometer Imperfections

Most SSS methods operate by compensation. For instance, one part of the excitation sequence moves the solvent magnetization away from O_z , another brings it back. Errors in *pulse amplitude*, *phase*, *timing* or *frequency* may ruin the compensation. Such errors may be static, or they may vary slowly (drift) or rapidly (fluctuations).

Static errors (e.g., of the phase) may be compensated for, if the spectrometer has provisions for appropriate adjustment. *Drift* of frequency, timing, or phase of the rf pulse generator should not be a problem in a spectrometer that is reasonably built and operated. The main sources of drift are the power amplifier, the temperature controller and the field/frequency lock. If the deuterated compound used for locking is not D₂O, the relative chemical shift of water will be changed by temperature drift, affecting SSS. Instrumental *fluctuations*, i.e., variations on the timescale of the SSS sequence, directly affect the compensation between pulses. They are easily observed as fluctuating differences between successive residual solvent signals following SSS excitation. For instance, we measured phase fluctuations of 1/1600 rad in the time between the two JR pulses. For a preliminary and easy measurement of the spectrometer fluctuations, one may look for fluctuations of the nominally null dispersion component of the free precession of a strong signal at the excitation frequency.⁷

4.2 Modern Spectrometers

Modern spectrometers have improved agility—meaning the capability of shaping rf excitation to high resolution in amplitude, phase, and frequency as a function of time. With the help of optimization techniques and/or on the basis of the Bloch equations, one may then impose desirable conditions on the excitation sequence. A recent example is a flexible procedure for the design of an excitation spectrum identical to any available NMR spectrum.³⁴ New SSS sequences may now be endowed with many more parameters, and they may be designed, for instance, with the aim of obtaining constant phase and amplitude across the spectrum, except for a 'notch' at the solvent frequency.³⁵ Earlier SSS sequences can be revised by changing the pulse shape (from square to Gaussian, half-Gaussian, etc.) and phase. SSS will certainly benefit from the enhanced agility. However, the benefits should be limited, because pulse sequences with improved selectivity properties tend to be longer.

Probably more important for SSS is the improvement in stability and quality of the rf pulse generators, which should result in better results with a given SSS sequence.

Another important feature of modern spectrometers is the generation of a pulsed gradient of the main field, resulting in the destruction, and possibly the later recall, of any transverse magnetization existing at that time. SSS sequences using a

pulsed field gradient have been mentioned above, for example, the WATERGATE sequence (Section 3.1). Potential problems are the distortion of the pulsed field gradient by eddy currents and the perturbation of the field lock system during the pulse. An rf field gradient, which may provide the same benefits as a gradient of the main field, does not have these problems,³⁶ and could come into current use.

4.3 Evaluation Procedures and Test Samples

Detailed study of the performance of a method and of a spectrometer is usefully complemented by a global test, namely, the spectrum of a standard sample, designed to provide clear indications of the suppression factor, the sensitivity, and the type and amount of data processing required. We suggest a standard sample containing thymidine in H₂O, at a concentration of 10 mM. The excitation sequence should maximize the imino proton line, at -11.1 ppm. The spectrum should extend up to 1 ppm, exhibiting the aromatic, ribose, water, and methyl lines. A similar sample, but in D₂O, should be used for comparison. The spectrum should be examined, both before and after data processing, for reduction in sensitivity, artifacts, distortions of peaks and baseline, and reduction in visibility of lines close to the solvent line. Such defects are more important than the residual solvent signal per se. Figure 6 shows an application to the JR sequence.

5 DATA PROCESSING FOR SSS

The free precession resulting from SSS excitation, although it is within the dynamic range of the NMR receiver, may still contain a large solvent signal, which must be further reduced by postacquisition data processing. Data processing is invariably based on prior knowledge of the signal to be reduced (e.g., its frequency). It is carried out either in the time or frequency domain.

The elimination of a (solvent) signal on the basis of its frequency may be obtained with a frequency filter, which will strongly attenuate all of a Lorentzian centered at the filter frequency. For instance, subtracting from a FID its time-shifted copy filters out a signal at zero frequency.³⁷ Unfortunately, this convenient method introduces a linear phase shift.

A frequent defect of SSS spectra is the 'rolling baseline' resulting typically from linear phase correction acting on the solvent line. More or less empirical methods for baseline correction are usually provided on commercial equipment. The results are far from perfect. Worse, they may lead to systematic errors, for instance, in integration. To avoid this, the solvent signal should be eliminated before attempting linear phase correction. In our opinion, the best method is to treat the residual solvent signal as a collection of Lorentzians, which are simulated and subtracted recurrently, one at a time.⁷ The procedure is fast and distortionless. It may be made entirely automatic (Figure 6). The general methods of maximum entropy³⁸ or linear prediction³⁹ may also be used.

In most SSS methods, the gain is a function of frequency, or, more precisely, the amplitude of a Lorentzian is a function of its center frequency. A frequency-dependent amplitude correction restores each Lorentzian peak to its correct height.

This does produce distortions, but they are much less severe than those caused by phase correction.

Further spectral distortions in phase and amplitude arise owing to the noninfinite strength of the b_1 field (such effects motivate the use of PJR instead of JR). As a first step towards correcting these defects, it would be useful and possible to provide NMR spectrometers with software that would calculate amplitude and phase shift for an arbitrary excitation sequence.

6 SOLVENT SIGNAL SUPPRESSION IN 2D AND 3D NMR

This section, mainly contributed by A. G. Redfield of Brandeis University, is to a large extent based on limited personal experience. Therefore, references to recent excellent work may in some cases be inadvertently omitted.

6.1 General

We shall assume general familiarity with established methods and notations of 2D NMR.^{40,41}

The solvent signal is not nearly so large a problem in 2D and 3D NMR as it is in 1D NMR, because, generally, one is interested only in cross peaks between two lines in the spectrum, and most often one of these is located far enough from the water peak to be observable with relatively simple means such as water presaturation. Cross peaks are commonly observable to protons of the amide and β -carbons, from protons of α -carbons that are within a few tens of hertz from the water resonance, and in some cases NOEs from peaks directly underneath water are observable. Furthermore, most 2D studies have been performed on extremely small biopolymers, i.e., proteins smaller than 15 kDa, or nucleic acid duplexes smaller than 15 base pairs. For these small molecules, the loss of signal by cross relaxation to saturated water⁴² is relatively small. And, since the object of 2D NMR has often been primarily to determine structure, rather than study kinetics, the pH can often be chosen to minimize the other process of signal loss when water is saturated, namely, chemical exchange with water.

Furthermore, the nature of many 2D experiments is such as to cancel and filter out the direct effect of water signals and other large signals. Most heteronuclear 2D methods, and certain homonuclear methods such as double quantum filtered COSY,⁴¹ are in this class. Especially for these experiments, the baseline roll far from water is not a problem. It is also often not a problem for many experiments, such as NOESY, where a large residual water self-peak does occur, because usually one of the two protons giving rise to interesting cross peaks is far from water, as mentioned above.

For these reasons, SSS methods have not been developed as intensively for 2D NMR as they have been, for example, by practitioners of *in vivo* NMR. Nevertheless, there is a need for continued development. Partly because each FID in a 2D data set results from the accumulation of only a few (typically 4–32) individual signals, averaging of random water signals due to random phase errors in selective sequences, or in water saturation, is not as effective as it is in some 1D experiments. These random signals result in random baseline variation in

each 1D spectrum obtained from the 2D data set by Fourier transformation (FT) with respect to the real-time dimension t_2 , before FT in the second, evolution or t_1 , dimension. As a result, there is an ugly stripe in the final 2D spectrum along the line corresponding to the solvent frequency in the f_1 dimension, exhibiting streaks extending roughly 1 ppm in the f_2 direction. Similar noise emanates from residual HDO in D_2O solvent, if HDO is not saturated, and from other strong signals such as buffer signals.

These streaks are known as ‘phase noise’, and they can often be reduced by computer flattening of the baseline of each spectrum after the FT in the t_2 dimension, or by other operations on the frequency domain spectrum based on the known frequency of water,⁴³ by time domain removal of the low-frequency water signal,⁴⁴ or by simple convolution difference weighting. The latter weighting produces undesirable troughs near the diagonal ridge. We often work with two 2D FTs of the same spectrum, one with heavy convolution difference weighting for finding cross peaks close to the water phase noise line, and another with little or no such weighting, to find peaks close to the diagonal. It is desirable to have software conveniently set up for such treatment. If convolution difference weighting is used, it is important to have a versatile weighting function for which the convolution difference weighting, at the beginning of the FID, can be varied independently from the line broadening or enhancement functions (affecting the middle of the FID) and from apodization (at the end of the FID). The commonly used shifted sine-bell function does not have this quality.

Water presaturation in 2D NMR is often performed in much the same way as in 1D NMR. It is often desirable to saturate water with a sequence (such as a spin lock pulse) that acts for a short time just before the start of the sequence, rather than a saturation pulse during the entire recovery time. Doing so decreases the number of protons that will be cross saturated by water, at the cost of a wider spectral region of saturation. After selective presaturation of water and, unavoidably, of α -protons whose frequency is close to, or even at, the water frequency, one can take advantage of the short cross-relaxation time within the protein compared with the T_1 of water to restore quickly the polarization of the α -protons. One can thus observe NOESY cross peaks to these protons.⁴⁵ Water saturation is also used in the middle of 2D or 3D sequences.⁴⁶ In heteronuclear sequences, one can saturate water once heteronuclear correlation has been established,⁴⁷ because water is not involved in the correlation. A simple modification of the excitation sequence for generating heteronuclear magnetization transfer provides a time window when the heteronuclear correlation is along Oz . At that time, a gradient pulse¹⁰ can be used to destroy selectively transverse water proton magnetization. In such a scheme, SSS is based on the lack of J coupling of the water protons to the heteronucleus. There is no need for any frequency-selective sequence.^{48, 49}

Three-dimensional NMR offers no problems beyond 2D NMR, as far as the solvent signal is concerned.

6.2 Selective Excitation in 2D NMR

Water saturation is less desirable for studies of larger proteins,⁴² studies at a pH far from the minimum (pH = 4) for the rate of proton exchange with solvent, and the

study of nucleic acids, whose water accessibility and smaller diameter promote cross relaxation to water. In these cases, selective sequences are useful. We discuss the approach in some detail, because we think it may be useful for 3D NMR in larger proteins, where good signal-to-noise ratio will become a serious consideration.

6.2.1 Fully Selective Excitation

Fully selective 2D heteronuclear multiple quantum coherence NMR, or HMQC, may be implemented using a JR-type selective pulse sequence in place of every $\frac{1}{2}\pi$ or π proton pulse in the sequence.^{50, 51} This has the advantage that water, being unperturbed, can act as a magnetization reservoir for the macromolecular spin system. Perturbation of the exchangeable protons is also avoided—a matter of importance for NMR of nucleic acids, and sometimes of proteins. The JR sequence has the advantage of being short and of not generating phase dispersion. A selective pulse sequence with a broader zero, such as 214 (Section 3.2.1), may be even better, because it can be set to excite predominantly the high-frequency amide region and not the region of the aliphatic protons, to low frequency of water. This is useful, because, to some extent, these protons can act as a magnetization reservoir, like those of water. We have obtained HMQC spectra using 214 in place of each pulse, but have not yet established whether or not 214 is more useful than JR in practice.

In HMQC, as in many other procedures, a proton π sequence is required in order to refocus unwanted proton evolution. Generally, for this purpose, we have used either back-to-back JR pulse sequences, or—what is nearly the same—a JR sequence with roughly twice the spacing of the ‘traditional’ JR sequence. An alternative, which requires a good magnet and rf field, is to use carefully adjusted π pulses. If these pulses occurred in pairs in the sequence (accomplished, if necessary, by adding an initial π pulse), the water resonance would remain relatively unsaturated. We have not yet attempted to use this approach.

There were two unexpected aspects of our use of JR for proton $\frac{1}{2}\pi$ and π sequences in HMQC. First, we eventually discovered that the primary amide ($^{15}NH_2$) region of the protein spectrum has complicated side-peak artifacts when selective JR sequences are used, compared with the expected two peaks at the same ^{15}N shift that are actually observed when HMQC is performed with water presaturation and hard $\frac{1}{2}\pi$ and π pulses. We do not have a quantitative explanation for this difference. But, once recognized, it is useful for distinguishing the primary amide peaks of glutamine and asparagine side chains from peptide NH peaks.

A second unexpected result of the use of a selective π sequence in HMQC is that, because the sequence is also relatively ineffective for perturbing the α -protons (whose chemical shift is close to that of water), it suppresses a splitting in the ^{15}N dimension due to the coupling of the α -proton to nitrogen, which would otherwise degrade resolution.⁵² It is generally desirable to avoid this splitting.

6.2.2 Mixed Excitation; Gradient Pulses

In some cases, fully selective excitation is undesirable because cross peaks to water or to α -protons will be suppressed. In these cases, it is often—perhaps always—possible

to use nonselective pulses as necessary within the first part of the sequence, and to use an SSS sequence in place of the last, read-out pulse. Before read-out, the large transverse water signal, which generally results from the first, 'hard' part of the sequence, must be destroyed—usually by application of gradient pulses placed so that they do not affect the evolution of the spins to be observed.

An example of this approach is the 'hard-soft NOESY' sequence,⁵³ in which the two encoding pulses are hard, the water signal is removed by relaxation or a gradient pulse during the mixing time, and SSS read-out follows. However, in high-field spectrometers equipped with efficient probes, there is a problem with this sequence when the first two pulses are phased so that they make the water magnetization negative: during acquisition, a residual water signal will then be amplified maser-like, by the phenomenon of radiation damping. For this phase combination, the SSS read-out subsequence should be replaced by one that, while not generating a transverse water signal, reverses the longitudinal water magnetization.⁵⁴

A very useful example of mixed excitation is the use of a 'Z filter'⁵⁵ at the end of TOCSY (also called HOHAHA) or ROESY (also called CAMELSPIN) excitation. These are spin lock sequences, and it is difficult (but probably possible) and not very useful to make them water-selective. However, at the end of such a sequence, the magnetization can be flipped up to the z axis with a hard $\frac{1}{2}\pi$ pulse, and the residual transverse component of magnetization removed with a gradient pulse and/or appropriate phase cycling. Then, after a short homogeneity recovery delay, the final selective sequence is applied.⁵⁶ This is the method of choice to obtain amide- α -proton covalent correlations when water saturation is undesirable. The Z filter (as used here) functions exactly as the last two pulses of a Hahn stimulated echo.

The Z filter just described cannot generally be appended to a COSY or related sequence involving two-spin coherence. However, it seems likely that useful COSY and stimulated echo⁵⁷ homonuclear sequences could be assembled from combinations of selective pulses and gradient pulses.

Similar approaches have been applied to isotopically enriched proteins, in combination with heteronuclear selection, for the study of cross relaxation between amide and α -protons,⁴⁸ and also between amide protons and water.⁵⁸ In the latter work, frequency-selective subsequences are used to keep the solvent magnetization along the $+z$ axis except during the mixing period. Gradient pulses are used to destroy residual transverse magnetization, in order to avoid radiation damping artifacts and to enhance SSS. Applied in this way, they do not contribute to saturation of the solvent resonance. In particular, the final 'observe' subsequence is a WATERGATE-type sequence (Section 3.1) modified so as to avoid solvent saturation.

7 CONCLUSIONS

Proton NMR in protonated solvent used to be such a difficult proposition that it was carried out only if absolutely necessary—in particular for the study of exchangeable protons. Alternative approaches, such as NMR of nonexchangeable protons or of other nuclei, were much preferred. The situation has changed: SSS has become so simple that

exchangeable protons are now a fruitful and relatively easy subject of investigation. It is now worthwhile to work in protonated water simply to avoid the H_2O -to- D_2O transfer of a precious protein. The mastering of NMR in protonated solvents leads to the highly sensitive reverse INEPT detection of ^{15}N , thus making possible studies of ^{15}N -labeled macromolecules that would have been impossible or very difficult previously. SSS is also applied to proton NMR spectroscopy of organs and organisms—a case where the solvent cannot be changed.

The value of signal solvent suppression stimulates methodological research, which is thriving if one gauges it by the number of publications. SSS methods also evolve as new equipment and processing software becomes available. They will benefit from enhanced stability of the rf phase and of the magnetic field; frequency-agile synthesizers would promote new variants; faster data processing would diminish the requirements on SSS excitation and acquisition.

Novel methods could emerge from two relatively recent developments, both stimulated by the needs of medical imaging and spectroscopy. One is the introduction of precise and flexible phase and amplitude control of the excitation pulses. This facilitates the design of excitation sequences that produce a spin response with complex, predesigned phase and amplitude properties.

The second—and in our opinion more important—development is the introduction of fast switching gradient coils. They are affecting all manners of NMR experiments, including those involving SSS. Switched gradients quickly eliminate transverse magnetization, so that a gradient pulse applied after a selective $\frac{1}{2}\pi$ sequence provides saturation of the solvent magnetic moment in a time short enough to avoid most difficulties due to spin exchange or chemical exchange. When used with echoes, gradients may eliminate the need for EXORCYCLE cycling. With these new possibilities, SSS methods using slow saturation, and those giving rise to a linear phase shift are, or should soon become, obsolete.

1 INTRODUCTION

NMR spectroscopy has provided many new insights into the physiology of higher plants. There are a number of instances where NMR measurements of specific physiological parameters now constitute established methods. Other findings have been described by more limited numbers of investigators and/or with a limited number of plant systems, such that their importance and generality awaits future evaluation. The purpose of this chapter is to provide an overview of NMR studies of higher plants with respect to physiology. Hence the chapter is organized with respect to recognizable physiological functions.

The field of NMR spectroscopy of plants has been surveyed by several authors.^{1–7} Practical aspects of specific NMR measurements have also been presented.^{8–11} I have not cited every paper published in this field; the references provided will lead to the great majority.

2 NUTRITION AND METABOLISM

Since higher plants are autotrophs, the acquisition and metabolism of inorganic nutrients are processes that play a dominant role in determining plant performance. In addition, within the plant, the transport and partitioning of assimilated nutrients, such as sugars and amino acids, are central to plant growth and development. The following provides an overview of NMR investigations into these processes.

2.1 Carbon Assimilation and Metabolism

In 1975, Schaefer et al.¹² studied soybean ovules using *in vivo* ¹³C NMR, observing metabolites derived from atmospheric ¹³CO₂, fixed via photosynthesis in the leaf and translocated to the growing ovule. Since then, attention has been mostly given to nonreductive inorganic carbon fixation and metabolism ('dark CO₂ fixation'). Here, carboxylic acid groups of organic and amino acids are monitored by ¹³C NMR. Leaves of Crassulacean plants can fix inorganic carbon into malic acid in the dark such that by the end of the night the concentration of this acid can increase by more than 50 mM, with the chemical shifts of malate carboxylic acid resonances reflecting the pH in the vacuoles of the leaf cells.¹³ Even

though most of the malate that accumulates during the night is localized in vacuoles, Kalt et al.¹⁴ found a considerable flux of malate back out of vacuoles, into the cytoplasm and mitochondria during this period of malate accumulation. This conclusion was drawn from observation of ¹³C label in carbons 1 and 4 of malate. The initial carboxylation reactions label at carbon 4, whereas the mitochondrial enzyme fumarase will randomize the label between carbons 1 and 4; mass spectrometry demonstrated the existence of no more than one ¹³C label per molecule.¹⁵

Dark, inorganic carbon fixation in maize roots has been studied by Chang and Roberts^{16–18} who were able to resolve the distinct cytoplasmic and vacuolar malate pools. Since malate is synthesized and metabolized in the cytoplasm and mitochondria of plant cells, this NMR method is useful for monitoring the metabolically active pool of malate, which plays a critical role in many physiological processes.¹⁹ Chang and Roberts¹⁷ showed that the concentration of cytoplasmic malate varies with metabolic state, a result with implications for the regulation of such important enzymes as phosphoenolpyruvate carboxylase, discussed later in Section 3.5. Gout et al.²⁰ were able to demonstrate that, in cultured sycamore cells, the concentration of cytoplasmic malate is much higher than that of citrate, reflecting the distinct reactions and forces that regulate transport of these two organic acids into and out of plant cell vacuoles. These authors also examined the intracellular location of fumarase in sycamore cells, and confirmed that randomization of label between malate carboxylic acid groups takes place in the mitochondria.

The *in vivo* activity of carbonic anhydrase has been estimated by two different NMR methods. Holtum et al.²¹ used ¹⁸O isotope shifts of [¹³C]carboxylic acid signals in malate isolated from leaves of Crassulacean plants that had been fed ¹³C¹⁸O₂; carbonic anhydrase activity is reflected in the replacement of ¹⁸O by ¹⁶O from leaf water. Chang and Roberts¹⁸ used saturation transfer ¹³C NMR to observe directly exchange of carbon between CO₂ and HCO₃[–] in maize root tips. Both studies found a considerable excess of carbonic anhydrase activity over that of phosphoenolpyruvate carboxylase, which catalyzes the dark fixation of bicarbonate. Hence, the hydration of CO₂ does not appear to limit phosphoenolpyruvate carboxylase activity *in vivo*.

The definitive power of ¹³C NMR to elucidate pathways of carbon metabolism is illustrated by the work of Keeling et al.²² who followed the conversion of specifically labeled hexoses into starch in developing wheat grains. The question they addressed was whether or not hexose must first be converted to triose phosphates prior to transport into amyloplasts for starch synthesis. Such a pathway would randomize hexose carbons 1 and 6, 2 and 5, and 3 and 4. Keeling et al.²² found the limited randomization of carbons in glucosyl residues of starch derived from [1-¹³C] or [6-¹³C]glucose to be similar to that in the hexose moieties of sucrose, which was taken to reflect randomization events in the cytoplasm. Hence, these investigators concluded that during starch biosynthesis *in vivo*, amyloplasts primarily import carbon as hexose phosphates, not triose phosphates. Viola et al.²³ reached similar conclusions in their studies with potato tubers and bean cotyledons. There is potential for applying *in vitro* positional analyses of isotope enrichments using NMR to questions of metabolic fluxes, by an approach that parallels radioisotope studies.²⁴

2.2 Nitrogen Assimilation and Metabolism

Both stable isotopes of nitrogen, the naturally abundant ^{14}N and the rarer ^{15}N , give NMR signals and have been used to follow incorporation of inorganic nitrogen into amino acids and proteins. Use of both isotopes can provide somewhat complementary information, with ^{14}N spectra providing information on levels of the more abundant existing amino acid and inorganic pools,^{25–28} while ^{15}N can be used to probe pathways of assimilation.^{26,29} The resolution of *in vivo* ^{15}N spectra is generally better than that obtainable with ^{14}N . Thorpe et al.²⁶ observed the preferential uptake and assimilation of ammonium over nitrate in cultured spruce buds using ^{15}N NMR. Moreover, these investigators reported that external ammonium was required, in addition to nitrate, for induction of the enzymes of nitrate assimilation. Concerning the pathway of ammonium assimilation, ^{15}N NMR reports support the view that the glutamine synthetase–glutamate synthase pathway dominates over incorporation via glutamate dehydrogenase, since the first metabolite labeled with ^{15}N after feeding $^{15}\text{HN}_4^+$ is the amide nitrogen of glutamine.^{26,29} Glutamate dehydrogenase appears to have a catabolic function,²⁹ a role mandated in part by very low cytoplasmic ammonium levels (which would necessarily limit ammonium assimilation via glutamate dehydrogenase) that have been estimated indirectly from cytoplasmic and vacuolar pH estimated using ^{31}P and ^{13}C NMR, and total intracellular ammonium measurements.³⁰ Intracellular ammonium is largely trapped in the acidic vacuoles because of the high permeability of biomembranes to NH_3 , such that the ratio of NH_4^+ concentrations approaches the ratio of H^+ concentrations.

Solid state ^{13}C and ^{15}N NMR methods have been used by Schaefer and his colleagues to obtain a comprehensive picture of amino acid and ureide metabolism into storage protein of developing soybean cotyledons^{31–36} (reviewed by Roberts^{1,4}).

2.3 Cation Uptake

The transport and compartmentation of nonmetabolizable cations has been the subject of relatively few NMR studies, in contrast with the considerable amount of literature available on this agriculturally very important topic. This is due primarily to the electrical quadrupole moment of the NMR-active Group 1 and 2 nuclei. The uptake of ^{23}Na by plant cells has been monitored using extracellular dysprosium shift reagent to separate intra- and extracellular sodium NMR signals.^{37–39} The uptake and compartmentation of ^{133}Cs (a potential analog of potassium) can be studied without shift reagents, because the different environments of cytoplasm, vacuole, and external solution lead to distinct chemical shifts and relaxation times.^{40,41}

The transport and compartmentation of Mn^{2+} has been followed indirectly, using signals from anions containing ^{31}P ^{42–44} or ^{13}C ,^{16,20} and signals from water in leaves.⁴⁵

2.4 Phosphate Uptake and Metabolism

Phosphorus-31 NMR has been widely applied in plant physiology research, and a number of ^{31}P NMR studies are discussed in Section 1. The separation of cytoplasmic and

vacuolar inorganic phosphate (Pi) signals in plant tissues⁴⁶ allows both the uptake and compartmentation of phosphate to be followed by NMR, together with the incorporation of phosphorus into the more abundant, freely mobile, low molecular weight metabolites such as nucleoside triphosphates, sugar phosphates, and sugar nucleotides.^{47–49} Relatively few studies have been quantitative, using units recognizable by biochemists. Inspection of the following works provides one with a view of the complexities. Lee et al.⁴⁹ provide us with a valiant analysis of some published data on the concentration of cytoplasmic Pi . In 2 mm-long maize root tips, conversion of measured cytoplasmic Pi contents ($\mu\text{mol g}^{-1}$ of tissue) to cytoplasmic concentrations does not involve application of large conversion factors, since cytoplasm occupies most of this tissue. Using an external reference compound in a sealed capillary, Roberts et al.⁴⁷ and Pfeffer et al.⁴³ (see also Lee et al.⁴⁹) estimated the cytoplasmic Pi concentration in glucose-fed oxygenated maize root tips to be $\sim 2\text{ mM}$. Using a reference compound contained in the perfusion medium and in the absence of exogenous glucose, Lee et al.⁴⁹ estimated a cytoplasmic Pi concentration of $\sim 6\text{ mM}$. It is not clear if differences between these results arise from some methodological factor, possibly flow effects associated with use of a circulating external standard or the physiological condition of the root tips (sugar depletion and low oxygen status can increase cytoplasmic Pi concentrations by $\sim 50\%$ and 250% , respectively⁵⁰). Studies of cultured sycamore cells have led to cytoplasmic Pi estimates of $0.8\text{--}1.2\text{ mM}$.⁵¹ In nonilluminated spinach leaves, the analysis of Bligny et al.⁵² indicates that the cytoplasmic (extrachloroplastic) Pi concentration is less than 2 mM .

The activities of several enzymes involved in phosphorus metabolism have been studied by ^{31}P NMR. The synthesis of adenosine triphosphate (ATP) from cytoplasmic Pi under steady-state conditions has been measured using saturation transfer NMR methods in maize root tips^{50,53} and rice shoot tips.⁵⁴ This technique has also been applied to the exchange of phosphorus between glucose 1-phosphate and uridine diphosphoglucose (precursor to cell wall polysaccharides and sucrose).⁵⁵ Reactions slower than those just mentioned can be studied under non-steady-state conditions by following the intensities of specific resonances. Assignment of changes in a particular resonance to an individual biochemical reaction is complicated by the fact that often the unidirectional rates of synthesis and breakdown are both much higher than the rates of net synthesis or breakdown. Gout et al.⁵⁶ studied the transport of phosphorylcholine in cultured sycamore cells, demonstrating that this component of the xylem fluid is rapidly hydrolyzed in the cell wall, the products of hydrolysis being taken up separately, with the choline being phosphorylated in the cytoplasm by choline kinase.

3 RESPONSES TO THE ENVIRONMENT

The immobility of higher plants makes them prone to all manner of physical and biological insults, which they must therefore withstand for survival and success. Determination of the mechanisms by which higher plants withstand and adapt to different environments is of paramount importance for our understanding of natural, urban, and agricultural ecosystems.

The following sections outline how NMR has provided insight into plant responses to the environment.

3.1 Hypoxia

Low oxygen environments are commonly encountered by plant roots and entire, young seedlings when the soil becomes flooded, due to precipitation and runoff exceeding drainage. Hypoxia suppresses oxidative phosphorylation, so that plant tissues are forced to rely more on pathways of fermentation. A number of NMR studies have identified the importance of prevention of cytoplasmic acidosis if the plant is to survive prolonged periods of severe hypoxia,^{57–62} and these studies have shown that a key factor is reduced fermentation to lactic acid (or the induction of a lactate excretion system), since these traits correlate strongly with survival. The apparent simplicity of this result, which has come from studies with divergent species and tissues, is perhaps surprising given that many reactions other than lactic acid synthesis can contribute to pH regulation in plants.^{18,58,63–65} This result demonstrates that the relative importance of these many reactions that can influence intracellular pH remains to be evaluated critically.

Metabolic transformations in plant tissues during hypoxia have been studied by ^{13}C ,^{57,62,66} ^1H ,^{54,67,68} and ^{31}P NMR.^{53,54,60}

Hooks et al.^{69,70} described the physical state of nucleotides in maize root tips, using ^{31}P NMR and *in vitro* analytical techniques. Much of the cellular nucleoside diphosphate in oxygenated root tips is NMR-invisible, a significant proportion of which is due to immobilization on macromolecules, which have high affinities for ADP and guanosine 5'-diphosphate. Under hypoxia, the levels of NMR-visible, free nucleoside diphosphate increase several-fold, and much more than the levels of total cellular nucleoside diphosphate. In contrast, virtually all of the cellular nucleoside triphosphate in both hypoxic and oxygenated tissue is detectable by NMR. However, ^{31}P relaxation measurements of nucleotide resonances are consistent with the idea that when ATP levels are reduced by hypoxia, most of the ATP is associated with macromolecules (the bound nucleoside triphosphates being in rapid exchange with nucleotides in free solution). It was concluded that the free energy available to drive metabolism in oxygenated cells is much higher than that deduced from measurements of total cellular nucleotides, and similar to the values estimated by *in vivo* ^{31}P NMR. In contrast, for hypoxic cells, both *in vivo* NMR and extract analyses overestimate the available free energy of ATP hydrolysis (see also Roberts⁶⁵). This view would account for the fact that processes such as protein synthesis and ion transport are so sensitive to hypoxia even though ATP levels often decrease by little more than 60%.

3.2 Starvation

Nonphotosynthetic plant tissues, and green cells in the dark, rely primarily on carbohydrates for their energetic needs. Either internal stores of starch, or sucrose donated by other cells via the phloem, feed into the glycolytic and pentose phosphate pathways. The effects of carbohydrate deprivation on phosphorus metabolism in cultured sycamore cells has been studied by Roby et al.⁵¹ The restriction in carbohydrate metabolism could be followed in detail by observation

of the decline in glucose 6-phosphate and uridine diphosphoglucose ^{31}P resonances. It was only when the signals from these metabolites were reduced considerably that nucleoside triphosphate began to fall, this latter change being accompanied by accumulation of phosphorylcholine in the cytoplasm. This response reflects cellular autophagy of membranes consumed for energy production during carbohydrate starvation. Natural abundance ^{13}C NMR studies of cell extracts during carbohydrate starvation indicated that the autophagy also involved catabolism of cellular protein, reflected in the elevated levels of many amino acids, the most prominent being asparagine.⁷¹

3.3 Salt

Soils in many regions of the world are naturally high in soluble salts. Moreover, many of the world's richest agricultural areas, which rely on extensive irrigation, face possible doom (the fate of civilization's past) from the salt residue left behind after prolonged evaporation of irrigation waters. Stress from salinity not only increases as a function of soil water salt concentration, but also with the concentration of specific ions. For example, the effects of high sodium ion are influenced by the presence of calcium, at the level of both soil structure and plant physiological response. There is also the difference between treatments involving almost instantaneous increases in salinity (salt shock), and those which employ more gradual applications of stress (this is an issue also in studies of plant responses to factors such as oxygen).

Roberts et al.⁴⁷ described the enhancement of Pi uptake in salt-treated (0.1 M NaCl/10 mM CaCl_2) maize root tips, from a solution containing 10 mM Pi. These authors estimated the cytoplasmic Pi concentration to be just under 2 mM. Hence the enhanced uptake may simply reflect increased passive influx of Pi, due to an increased permeability of the plasma membrane in the presence of salt. This treatment caused an increase in the cytoplasmic Pi concentration, and an increase in the level of cytoplasmic Pi relative to other cytoplasmic phosphates. This inability to regulate cytoplasmic Pi, in contrast to the behavior of nonstressed plant cells exposed to exogenous Pi,^{48,72,73} may lead to the increase in Pi transport from roots to leaves which, in turn, can result in symptoms of phosphorus toxicity and reduced yield in salt-stressed maize plants fertilized with high levels of Pi.⁴⁷

Spickett et al.⁷⁴ examined the effects of increased exogenous salt and nonionic osmotica on maize roots using ^{31}P NMR. These stresses induced increases in levels of phosphorylcholine, indicating breakdown of phosphatidylcholine (as observed in the starvation studies noted above), and vacuolar Pi, which was attributed to breakdown of NMR-invisible constituents such as nucleic acids and phospholipids. In contrast to vacuolar Pi, cytoplasmic Pi increased only transiently. These effects, and the observed cytoplasmic alkalization, led the authors to postulate that a plasma-membrane-associated phospholipase is activated following a decrease in cell turgor, and that this and other enzymes may form part of the transduction system that senses, and may signal a response to, the stress. Spickett et al.³⁹ went on to study changes in intracellular pH in salt-stressed maize root tips using ^{31}P NMR. Since this tissue takes up significant quantities of sodium ion, which was followed by ^{23}Na NMR, these workers analyzed observed

changes in the chemical shifts of cytoplasmic and vacuolar Pi resonances with respect to changes in both pH and mineral ions, since both can significantly influence ^{31}P chemical shifts.⁷⁵ Despite these complications, Spickett et al.³⁹ were able to conclude that salt treatment led to a small cytoplasmic alkalinization (0.1–0.2 pH units) and a larger vacuolar alkalinization, as was also reported for barley by Fan et al.⁷⁶ These pH changes were interpreted as reflecting activation of the tonoplast H^+ -ATPase, and operation of a tonoplast H^+/Na^+ antiporter.

3.4 Heat

The aerial parts of plants commonly experience wide variations in temperature, such that during the life of a plant only a small fraction of time may be spent at an optimum temperature. McCain et al.⁷⁷ have used ^1H NMR to monitor the integrity of the membrane that surrounds the chloroplast (the envelope). These investigators have shown that the ^1H NMR spectra of leaves of certain species (notably many trees) have two principal water signals: one from water in the chloroplast, the other from water in other compartments.¹⁰ McCain et al.⁷⁷ found that with increasing temperature, the chloroplast water signal lost intensity and shifted upfield, further from the nonchloroplast signal, which increased in intensity. These changes occurred at a quite well-defined transition temperature range, and indicated a sudden loss of water from the chloroplast. These temperature-induced changes at the level of the envelope were not correlated with events associated with loss of thylakoid membrane function, followed by fluorescence, which indicates that these two spectroscopic approaches provide distinct perspectives on chloroplast function in intact leaves.

3.5 Extremes in Extracellular pH

The pH outside root cells will depend on the soil environment, influenced by such factors as lime content, fertilizer application, microbial activity, and aeration. The external pH of all plant cells may be impacted by levels of such factors as CO_2 and the pollutants of acid rain.

Two groups have carefully studied the regulation of intracellular pH in cultured cells exposed to different external pHs. Using ^{31}P NMR, Fox and Ratcliffe⁷⁸ found that cytoplasmic pH in oil palm and carrot cells was independent of external pH over the range of 5.5 to 8, if external pH was altered slowly. Outside of this range, responses were complex and time-dependent, including overcompensation during recovery from exposure to alkaline external pHs. Gout et al.⁷⁹ added to this knowledge by using both ^{13}C signals of citric acid and ^{31}P signals as intracellular pH indicators in sycamore cells, since these provide a sensitive picture over a wide range of pH values. Both cytoplasmic and vacuolar pH were quite independent of external pH over the range of 4.5 to 7.5, whereas outside of this range both intracellular compartments tended toward the external pH value, the effect at acidic pHs being sharper. Insight into the biochemical reactions underlying this pattern of intracellular pH regulation was provided by measurements of oxygen consumption. These measurements showed that respiration increased as external pH

decreased from 7.5 to 4.5, this change being accompanied by a decrease in levels of nucleoside triphosphate, results which suggest that acidic extracellular pHs increase the demand for ATP, presumably due to activation of the plasma membrane H^+ -ATPase which struggles to offset the influx of protons from the medium. The threshold seen at pH ~ 4.5 , below which tight regulation of intracellular pH was not maintained, occurred at the very pH where cell respiration was at the maximum. Hence, the failure of pH regulation at acidic pHs appears to reflect the demand for ATP by proton pumps exceeding the capacity of the cell to provide it. This attractive result implies that the exact range of extracellular pHs over which intracellular pH is maintained will depend on the cell type, and the physiological condition of the cells. Indeed, Gout et al.⁷⁹ show how Pi starvation has an impact on the ability of plant cells to respond to acidic environments.

The gradual rise in intracellular pH that occurs as extracellular pH increases above 8 is accompanied by a net synthesis of malate and citrate.⁷⁹ This result is anticipated by the classical literature, which describes the ability of plant cells to convert neutral sugars to carboxylic acids, thereby counteracting reactions that generate alkali (such as OH^- influx). An unsettled question on this phenomenon, however, is exactly what signals the activation of the enzymes responsible for organic acid synthesis, notably phosphoenolpyruvate carboxylase. Gout et al.⁷⁹ speculated that it may be an increase in levels of cytoplasmic bicarbonate which activate this enzyme. This potential regulatory mechanism is one of several that have been proposed over the last few decades, and was explicitly examined by Chang and Roberts¹⁸ in maize root tips, with respect to the activation of organic acid synthesis by exogenous potassium. They measured bicarbonate influx and the amount of cytoplasmic bicarbonate derived from both respiration and the external medium and found not only no differences in these parameters when phosphoenolpyruvate carboxylase activity changed, but also that the concentration of cytoplasmic bicarbonate was approximately two orders of magnitude higher than the K_M of phosphoenolpyruvate carboxylase for bicarbonate, measured *in vitro*. These results argue against the idea that organic acid synthesis in maize root tips is controlled by the availability of bicarbonate. It is possible that this may not be the case in cells that exhibit lower rates of respiration than maize root tips. It is also possible that the affinity of phosphoenolpyruvate carboxylase for bicarbonate *in vivo* is not the same as that found by enzymologists.

Another sometimes popular hypothesis regarding the regulation of phosphoenolpyruvate carboxylase invokes changes in intracellular pH as the key regulatory event. The status of this idea in the literature is unsettled, and is the subject of several discussions concerning both NMR and non-NMR data.^{4,63,79}

If the extracellular space contains permeant acids or bases, then the effect of external pHs that are different from cytoplasmic pH can present a much greater challenge than the stresses just discussed. Guern et al.⁸⁰ imposed acid loads on cultured plant cells by adding to the medium aliquots of lipophilic acids, which penetrated the cells, liberating protons into the cytoplasm. Using ^{31}P NMR, these workers observed a large and rapid cytoplasmic pH drop, following addition of the acids. Significantly, after the initial drop in cytoplasmic pH, there was a partial recovery, a response of regulatory mechanisms that partially counteracts the effects of acid influx. Mathieu et al.⁸¹ concluded that the principal

processes responsible for cytoplasmic pH regulation under conditions of acid load were consumption of intracellular malate ('metabolic consumption' of protons), proton extrusion via the plasma membrane H^+ -ATPase, and other proton excretion mechanisms (see also Kurkdjian and Guern⁶³ for discussion).

3.6 Biological Agents

Plants are normally intimately affected by activities of other organisms including, at one end of the spectrum, the beneficial associations with symbiotic and free-living nitrogen-fixing bacteria, mycorrhizal fungi, and pollinating insects, to the generally benign microbes that live on leaf surfaces and around root systems and, at the other end, herbivores, pathogens, and pests.

Rolin et al.⁸² used ^{31}P NMR to study the symbiosis between soybean roots and the bacterium *Bradyrhizobium*, and were able to follow changes in vacuolar phosphate levels in root nodules under hypoxia or deprived of sugar. Subsequently, Pfeffer et al.⁸³ found that changes in vacuolar Pi signals under hypoxia were due to altered relaxation behavior of vacuolar ^{31}P in the cortical tissue of the nodule. These changes were postulated to arise from changes in viscosity, and occurred in parallel with changes in the water relaxation seen in images using NMR microscopy.⁸⁴ The observation of a signal from an unknown phosphodiester⁸² led to the isolation and structural solution of a phosphorylcholine-substituted glucan, produced by the bacterium.⁸⁵ This is a remarkable molecule, consisting of a 1.5 nm polyglucan ring, decorated on one side with a phosphorylcholine moiety. While the unusual structure of this molecule presumably is related to its function, its function is yet to be determined, although a role in osmoregulation has been suggested.

Horn et al.⁸⁶ examined the hypothesis that the response of plant cells to elicitors associated with pathogenic infection involves intracellular pH. These elicitors invoke a wide range of biochemical reactions that can constitute a global defensive response. Moreover, many of the reactions in this defensive response occur within just a few minutes. Both ^{31}P NMR and fluorescent dyes were used to follow intracellular pH immediately after addition of elicitors. They concluded that cultured soybean cells do not respond to elicitors by changing cytoplasmic and vacuolar pH.

1 INTRODUCTION

Wood is a heterogeneous material composed roughly of 40–50% cellulose, 18–35% lignin, 15–35% hemicellulose, and a smaller amount, 1–10%, of miscellaneous material collectively called extractives.^{1–4} The extractives are composed of tannins, starches, gums, fats, waxes, sugars, and resins. All of the carbohydrates, or what is left after removal of lignin and the extractives from wood, is called holocellulose. Whole wood has been studied by solid state NMR, and its components by both solid and liquid state NMR.⁵ Chars or activated carbons made from pyrolysis of wood at temperatures of about 650 °C or less are also suitable for study by solid state NMR. This article will only deal with solid state NMR of wood and wood chars. Solid state NMR, because of its nondestructive nature, can be used to study wood without chemical modification of the wood components or with less modification than would be needed to solubilize them. Most solid state NMR studies have used the ¹³C CP MAS technique for studies of whole woods or various components.⁶ The usual problems of quantitation in CP MAS, which have been reviewed for coals, will also apply to woods and especially wood chars.⁷ Quantitation problems have been discussed for wood with respect to the determination of carbohydrate and lignin content.^{8,9}

Articles on NMR of wood or wood components in both liquid and solid states can be found in a variety of journals, some of which are hard to find, especially at nonagricultural schools. Some journals not referenced here in which NMR wood articles often appear are *Holzforschung*, *Tappi*, *Appita*, *Carbohydrate Research*, *The Journal of Wood Chemistry and Technology*, and *Mokuzai Gakkaishi*.

1.1 Experimental Considerations

Most solid state NMR data of wood or wood components have been obtained with a single-contact-time (τ_{cp}) CP MAS experiment¹⁰ using contact times of 1 or 2 ms and pulse delays T_d of 0.5–10 s, with the longer times for pure cellulose. In the CP experiment, carbon magnetization is usually approximated as building up exponentially with a time constant T_{CH} , and dying out exponentially with a time constant $T_{1\rho}^H$. The experiment may be repeated, to increase the signal-to-noise ratio, with a time determined by T_1^H . For the data to represent the different carbon types fairly with one τ_{cp} , the following

conditions should hold for each nucleus $T_{CH} \ll \tau_{cp} \ll T_{1\rho}^H$ and $T_d > 5 T_1^H$. Several researchers^{8,9,11,12} have measured these parameters for wood components, and in one case⁹ a comparison has been made between the CP data and data from a single pulse experiment (SPE), which can be repeated in a time determined by the longer T_1^C .

The reported results for T_{CH} of the carbons in cellulose are 150 ms or shorter, with $T_{1\rho}^H$ values from 7 to 11 ms. For the nonprotonated aromatic carbons in lignin, T_{CH} values were found to be just under 0.5 ms, with $T_{1\rho}^H$ values from about 5 to 20 ms. The T_1^H value in cellulose was found to be 369 ms,⁸ and the values for lignin were less than 41 ms. The most slowly polarizing group in wood was found to be the carboxyl resonance from an acetate group in hemicellulose, where the T_{CH} was 0.8 ms.⁹ These researchers also compared CP experiments with contact times of 1 and 2 ms and a 1.5 s T_d with single pulse experiment (SPE) data using a 25 s T_d , and in all three experiments virtually all of the carbon was detected. However, at a contact time of 1 ms, the carboxyl region was underestimated in comparison to SPE data. These results agree with our data on coals, where carbonyl and carboxyl groups are the main functional groups underrepresented in CP experiments as compared with SPE. A 2 ms contact time and a 2 s pulse delay appears to be the best choice for the most quantitative data, although this might not be the maximum signal intensity.

2 WHOLE WOOD AND ITS MAJOR COMPONENTS

Wood can be studied by solid state NMR by looking at the intact wood or by breaking it into components such as cellulose, hemicellulose, and lignin. The different types of lignin are in fact defined by the procedure used to isolate them from the whole wood. Studying whole wood has the advantage that there is no modification of components as is the case in separation procedures. The different components all show characteristic resonances in the NMR spectrum, with some overlap of signals. One early NMR study on lodgepole pine shows spectra of the whole wood, the effect of ball milling on wood, two types of holocellulose, two hemicelluloses, cellulose and five types of lignin isolated from the wood.⁶

2.1 Cellulose

Cellulose, the major constituent of wood, is a linear homopolysaccharide composed of β -D-glucopyranose units. The empirical formula for cellulose is $(C_6H_{10}O_5)_n$, where n is the number of glucose monomer units in the polymer chain and is about 10 000 in wood cellulose and 15 000 in cotton cellulose.³ Cellulose is found in the form of microfibrils, which are the smallest structural units seen by an electron microscope. These microfibrils consist of a central core of parallel cellulose chains forming a crystalline region that is surrounded by amorphous cellulose and hemicellulose and encrusted and bound in the wood cell wall by lignin.^{1,13} The size of microfibrils varies, depending on the source, with the highly crystalline¹⁴ *Valonia macrophyssa* having about a 20 nm cross section and the crystalline region running at least 50 nm in length.¹³ The exact details of the fibrillar and

Figure 1 Basic structural units from wood components: cellobiose (1) unit in cellulose chain and guaiacyl (2) and syringyl (3) units from lignin

supramolecular crystal structure of cellulose is still open to debate.¹ All native celluloses have the same crystal structure called cellulose I, with four glucose units per unit cell and cellobiose (1) as the repeating unit in the chain direction with each glucose unit displaced 180° to give a twofold screw axis, (see Figure 1). There are at least three other crystal structures of cellulose (cellulose II, III, and IV). Cellulose II is more thermodynamically stable than cellulose I, because the crystal structure allows extra intermolecular hydrogen bonding between chains.

The ¹³C CP MAS spectra of cellulose from three different sources is shown in Figure 2. The spectrum of amorphous cellulose has four broad lines. Lines in an amorphous material are usually broader than for crystalline material owing to chemical shift dispersion. The most deshielded line at 105.7 ppm is assigned to the anomeric C-1 carbon, and the next most deshielded line at 84.7 ppm can be assigned to the C-4 carbon of the glucosidic linkage. The large unresolved peak between 70 and 80 ppm is assigned to the three other

ring carbons, C-2,3,5, and finally the nonring carbon, C-6, is assigned to the resonance at 63.1 ppm. The spectrum of powdered wood cellulose (Aldrich) is sharper than the amorphous cellulose, and two new sharp peaks at 89.6 and 65.9 ppm appear and can be assigned to carbons C-4 and C-6 of cellulose in the crystalline regions. The broad resonance between 70 and 80 ppm is now split also. The spectrum of cellulose from cotton is the most resolved of the three, with the anomeric carbon now showing a small splitting and with the sharp peaks at 90 and 66 ppm larger in comparison with broad shoulders at 84 and 64 ppm, showing this sample to be more crystalline than the wood cellulose. It should be noted that in cellulose the degree of crystallinity as measured by different techniques seems to vary with the technique.^{1,14} The NMR assignments for celluloses II and IV have also been given.¹⁵

2.2 Hemicellulose

Hemicelluloses are heterogeneous branched polysaccharides easily hydrolyzed by acid to their monomeric sugars consisting mainly of D-glucose, D-galactose, D-mannose, D-xylose, and L-arabinose. Also found are 4-O-methyl-D-glucuronic acid and galacturonic acid. The number of monomer units in a hemicellulose chain is about 200,³ the chains are branched, and there are acetate, methoxy, and carboxylic acid functional groups not found in cellulose. The structures of hemicelluloses in hard woods are also different than in soft woods.³ The ¹³C CP MAS spectra of hemicelluloses A and B have also been assigned.⁶ The general shape is somewhat similar to that of amorphous cellulose between 60 and 110 ppm, with the anomeric, C-1, carbon now at 103 ppm. Some additional resonances at 174 ppm are due to the acetate carboxyl groups, at 21.5 ppm from acetate methyls, and at 56 ppm from methoxy groups. Because clean separation of hemicellulose from lignin is difficult, small resonances from residual lignin can usually be seen in the aromatic region.

2.3 Lignin

Lignin is a highly aromatic irregular polymer of hydroxy- and methoxy-substituted phenylpropane units found in the middle lamella of plants, binding cells together, and in the secondary plant cell wall, encrusting cellulose microfibrils. Lignin in softwoods is composed mainly of guaiacyl units (2), while hardwood lignin is composed of syringyl (3) and guaiacyl units (2) (see Figure 1). Grass lignin is based on the *p*-hydroxyphenyl unit. However, most plants probably contain some of all three units. There are many methods used to isolate lignin from whole wood, and the name of the lignin is derived from the method (or the person who developed the method) used to isolate it. Because there are several types of ether and carbon-carbon linkages between phenylpropane units, there is great difficulty in isolating lignin without altering its chemical structure.

The ¹³C CP MAS spectra of three different types of lignin (Aldrich) are shown in Figure 3. Kraft lignin is isolated from the spent liquor during Kraft pulping, organosolv lignin is isolated from a mixture of hardwood chips by aqueous ethanol in the presence of mineral acids, and hydrolytic lignin is

Figure 2 Carbon-13 CP MAS spectra of three types of cellulose. All spectra were run with a 2 ms contact time and 1 s pulse delay

Figure 3 Carbon-13 CP MAS spectra of three types of lignin. All spectra were run with a 2 ms contact time and 1 s pulse delay

isolated from bagasse with superheated steam in the presence of acetic acid catalyst. In the NMR spectra, one can see major similarities and minor differences between the three lignins. All three show a very strong resonance between 50 and 60 ppm from methoxy groups on aromatic rings. The hydrolytic lignin also has a strong aliphatic resonance at 33.5 ppm from CH₂ groups not significant in the other two lignins. All three lignins show a resonance from carbonyl and carboxyl groups at about 206 ppm and 175–181 ppm respectively. The phenolic region between 145 and 153 ppm is very important in lignins, because (2) and (3) have slightly different resonances.⁵ The 153 ppm peak is assigned to the C-3 and C-5 carbons of (3), and the 145 ppm and the 148 ppm peaks are from the C-4 and C-3 carbons of (2), respectively. All three lignins in Figure 3 show a strong resonance at 148 ppm from (2), but only the organosolv and hydrolytic lignins show significant intensity from (3) at 153 ppm. Because of the large amount of oxygen substitution in the aromatic rings, *ortho* and *para* effects shift significant aromatic intensity from the protonated carbons to the more shielded region between 100 and 120 ppm. Spectra of Klason, dioxane, periodate, enzymatic, and Brauns native lignin have been discussed elsewhere,⁶ along with different Kraft preparations,¹¹ and comparisons between solid and liquid NMR spectra have also been given.⁵

2.4 Whole Wood

Some ¹³C CP MAS spectra of whole woods are shown in Figure 4 for three hardwoods (white oak, yellow poplar, and

Figure 4 Carbon-13 CP MAS spectra of four whole woods, three hardwoods (white oak, yellow poplar, and aspen), and a softwood (pine). All spectra were run with a 2 ms contact time and 1 s pulse delay

aspen) and a softwood (pine). All spectra are dominated by the resonances from cellulose (and hemicellulose) between 60 and 90 ppm and the anomeric carbon at 105 ppm. The one major notable difference in this region is associated with the yellow poplar sample. Judging by the size of the 89 ppm peak compared with the 84 ppm peak and the size of the shoulder on the 66 ppm peak, the cellulose in this sample may be more crystalline than in the other three samples. All four woods show acetate resonances at 174 and 21 ppm from carboxyl and methyl groups in the hemicellulose (and possibly lignin). There is no significant carbonyl intensity in the spectra of any of the woods, and all samples show a strong methoxy resonance at 56 ppm. Another difference among the four woods is in the phenolic region between 145 and 155 ppm. The hardwoods, white oak, and aspen have a larger resonance at 153 ppm from (3) than the 148–145 ppm resonance from (2). The opposite is true for the softwood pine sample, but also for the hardwood yellow poplar sample, showing the variability of lignin in hardwoods.

If spectra are taken under quantitative conditions, solid state ¹³C NMR can be used for the nondestructive determination of several structural parameters of whole (extractive free) woods. The parameters usually determined by solid state NMR are the total fraction of lignin in the wood,^{7,11} OCH₃/R, the number of methoxy groups per aromatic ring, and *f*_a^{a,H}, the fraction of aromatic carbon that has a proton attached as determined from dipolar dephasing experiments.^{8,16} These last two parameters give information on the basic lignin monomer unit and the ring substitution. One should note that in woods, the separation between the aromatic and aliphatic region is not as clean as in coals, owing to the carbohydrate C-1 carbons' deshielded resonance. While good results have been obtained by integrating the aromatic region from 109–110 ppm to the end of the aromatic range,^{8,11} the most quantitative results

require some estimate of the lignin contribution under the C-1 carbohydrate peak and also carbohydrate overlap of the lignin methoxy peak at 56 ppm.⁸

3 WOOD CHAR

Pyrolysis is the application of heat to a material in the absence of oxygen to degrade the material into solid, liquid, and gaseous phases. The remaining solid material, called char (or charcoal if the material was wood), has been historically used as a fuel. Sometimes, with chemical activation (H_3PO_4 or KOH), the pore structure of these chars (or activated carbons) can be increased, with the chars becoming highly adsorptive. The properties of these chars will depend on both the temperature and the time the wood has been heated. The products of pyrolysis of whole wood are basically what one would expect from pyrolysis of components separately. There have been very few reported studies of pyrolysis of wood¹⁷⁻²⁰ or wood components^{18,19,21} by solid state NMR spectroscopy.

Spectra from four activated carbons²⁰ made by pyrolysis of white oak (see Figure 4) are shown in Figure 5. Two of the samples were soaked in phosphoric acid for 1 h before pyrolysis. The 150 °C sample was slowly heated to temperature and held there for 3 h. The other samples were heated to 170 °C over 2 h, held there for 30 min, and then taken to their final temperature and held for 1 h. The 250 °C thermal-only sample has an NMR spectrum very similar to that of the starting material, except that the carboxyl and methyl groups from the acetate groups on hemicellulose have decreased in intensity and new resonances are starting to appear between 110 and 150 ppm from new aromatic (or alkenic) moieties and at 0–50 ppm from new aliphatic groups. In contrast, the acid-treated wood has lost all carbohydrate resonances by 150 °C, the spectrum is highly aromatic with a large new phenolic resonance at 147.5 ppm, a new carbonyl peak has appeared

at 204 ppm, and there are significant new aliphatic bands but with the lignin methoxy peak still visible. At 250 °C, the methoxy groups have left, aliphatic material has been lost or aromatized, carbonyl and carboxyl resonances have decreased, and the phenolic shoulder at about 150 ppm has been reduced in intensity. At 650 °C, only an aromatic peak can be seen. Underneath this peak, a very low intensity very wide band, probably from spins near free radicals, obscures any residual aliphatic material still present. The 650 °C spectrum is typical of that from the end product of pyrolysis of a carbonaceous material. On further heating, these types of material become too conductive to study by NMR.

Anisotropically Restricted Diffusion in MRI

Michael E. Moseley and Alex de Crespigny

Stanford University, CA, USA

1 INTRODUCTION

A dominant source of proton MR signal loss following radiofrequency excitation is caused by dephasing. While coherent flow will cause dephasing, other motions can contribute. One important mechanism of dephasing is that of a random *diffusion* of protons. This random phase shifting leads to signal loss because of phase cancellation. While T_1 and T_2 relaxation times reflect complicated frequency-dependent rotational and proton exchange processes, diffusion is caused solely by random proton displacements or translations through a tissue. Since the phenomenon of proton diffusion in vivo is complicated, the term ‘apparent diffusion’ described by the apparent diffusion coefficient, ADC , has been used to denote signal loss induced by random proton fluctuations. This applies to protons in water, phosphorus in high-energy metabolites, indeed to any MR-observable nucleus.^{1–3}

Considering water proton displacements in pure isotropic solutions, where the probability that a water proton will diffuse in any given direction is equal, the rate of random proton phase cancellation due to diffusion will be same regardless of the direction observed. This is termed ‘isotropic’ diffusion and is seen in homogeneous environments. In ordered environments, such as that found in liquid crystals for example, the resulting diffusion coefficient will depend on the direction of the motion being considered and on any geometric anisotropy created by the nature of the microenvironment.^{4,5} For water protons diffusing or moving within a tissue matrix, the observed diffusion rate and direction will reflect the molecular and macromolecular barriers or hindrances that the proton experiences during the translational process.

2 APPARENT DIFFUSION COEFFICIENTS AND OBSERVATION DIRECTION

Simply stated, proton apparent diffusion is slowed if the protons are hindered in their random motion.^{6–8} Hindrances can be impermeable barriers that completely restrict diffusion. In living in vivo tissues, however, water protons are probably slowed solely by the presence of membranes, cell walls, and macromolecules due to differences in water proton permeability. More specifically, myelin fibers and neurofibrils in white matter tracts possess a special hindrance for water proton movement which is greater in one direction than another. This causes protons to diffuse faster along any direction of least resistance, in this case along the long axis of the tracts, causing the apparent diffusion coefficients to be anisotropic or directionally-dependent. It is important to note that in vivo proton

diffusion is rarely restricted but is rather slowed by the presence and extent of permeable or semipermeable membranes. The complete concept of proton diffusion then is that of a tensor, where the diffusion rate or ADC value is a function of the diffusion direction in three-dimensional space.

As the tissue water protons constantly ‘experience’ the three-dimensional microenvironment through the processes of permeability, exchange, flow, and thermally-induced diffusion, their traveled path $\langle L \rangle$ along any one given direction (along the magnet bore direction, for example) can be estimated by:⁹

$$\langle L^2 \rangle = 2\Delta T(ADC) \quad (1)$$

where over an observation time of ΔT (s) the mean square displacement is expressed by an apparent diffusion coefficient, ADC (usually given in $\text{m}^2 \text{s}^{-1}$ or $\text{cm}^2 \text{s}^{-1}$). Typical proton diffusion coefficients, ADC , of $1 \times 10^{-5} \text{ cm}^2 \text{s}^{-1}$ are observed in cat cerebral gray matter,¹⁰ the average mean square displacement along that one given observation direction $\langle L \rangle$ becomes $(2 \times 40 \text{ ms} \times 10^{-5} \text{ cm}^2 \text{s}^{-1})^{1/2}$ or $9 \mu\text{m}$, observed over an effective observation time, (ΔT) , of 40 ms.

To date, most diffusion-weighted MR imaging and spectroscopy sequences have been based upon a spin echo Stejskal–Tanner (ST) sequence,^{11–13} either as the sequence itself or as a magnetization preparation set of prepulses, prior to another MR sampling scheme. Since the two ST ‘diffusion-sensitizing’ gradient pulses are symmetrical, all proton spin dephasing caused by the first diffusion-sensitizing gradient pulse will be refocused (spin-rephased) by the second diffusion-sensitizing gradient pulse for stationary spins. Randomly-moving spins (because of flow, perfusion, diffusion, etc.) will not completely refocus and will attenuate the observed echo or echo train. Note that mild coherent motions will result in phase shifts and not in signal attenuation without phase cancellation.

The observed echo or echo train signal intensity $S(Gi)$ can be expressed as:

$$S(Gi) = S(0)e^{-bD} \quad (2)$$

where the b value is defined^{12,13} by equation (3):

$$b = \gamma^2 \delta^2 G_\delta^2 (\Delta - \delta/3) \quad (3)$$

and $S(0)$ is the signal obtained without applied diffusion-sensitizing gradient pulses, γ is the gyromagnetic ratio, δ and G_δ are the duration and the amplitude of the diffusion-sensitizing ST gradient pulses along a given direction, Δ is the time interval between the leading edges of the diffusion-sensitizing gradients pulses and D is the water apparent diffusion coefficient (often expressed as the ADC value).^{12,13} Measurement of apparent diffusion from MR images would require plotting the natural logarithm of the image intensities against the b value. The slope of this observed monoexponential decay directly leads to a diffusion coefficient.¹¹

There exist three major advantages to using a ‘pulsed’ gradient approach for measuring in vivo diffusion. One is that the stronger pulsed gradient diffusion-sensitizing pulses overcome poor magnet homogeneity (which upon reflection, is a sort of residual magnetic field gradient itself).¹¹ Also, because the diffusion-sensitizing gradients are relatively short pulses, the time during which the sequence is sensitive to diffusion, $(\Delta - \delta/3)$, can be accurately controlled. From a knowledge of this obser-

vation time, $(\Delta - \delta/3)$, the mean path length can be estimated from the above Einstein displacement equation given the measured diffusion coefficient [equation (1)]. A final advantage is that the direction of the diffusion-sensitizing gradient pulses can be controlled accurately. All MRI scanners possess three orthogonal and linear magnetic field gradient coils, any or all of which can be pulsed to produce the diffusion sensitization, the effective angle of which is then the geometric sum of the pulsed gradients. This opens the path to mapping of the apparent diffusion tensor.^{14,15}

The complete concept of proton diffusion is then that of a tensor^{14,15} where the diffusion rate or *ADC* value is a function of the diffusion direction in three-dimensional space. Thus the tensor for free, isotropic, diffusion can be visualized as a sphere, with the same *ADC* in all directions, while the anisotropic diffusion of a white matter tract can be viewed as an ellipsoid tilted at some angle to the three principal axes, depending on the particular fiber orientation. Diffusion is then fastest along the principal or long axis of the ellipsoid, and takes a lower (but equal) value along the two orthogonal axes. The 'trace' of this ellipsoidal diffusion tensor is just the average of the *ADC* values measured along any three orthogonal directions, and is independent of fiber orientation thus yielding a useful measure of the average rate of diffusion without the complications of fiber directionality.

3 MAPPING AND THE ORIGIN OF THE APPARENT DIFFUSION ANISOTROPY

The *b* value-dependent diffusion effects on image intensity can be displayed in different ways. A diffusion-weighted image contains typically T_1 -, T_2 -, and diffusion-weighting, the amount of the diffusion-weighting being dependent on the *b* value. Within diffusion-weighted images, relative faster intravoxel motion will be observed as increased attenuation of the signal from that voxel, and consequently an observed hypointensity from that voxel as the *b* value is increased. Conversely, slower motions or diffusion leads to smaller signal attenuation. The observed result is that of regional relative hyperintensity. This is best seen in lipid regions outside the brain where lipid protons experience little or no diffusion because of the molecular size and environment of the long chain hydrocarbons.

A pure diffusion of *ADC* image is calculated from the acquisition of two or more images of varying *b* values. *ADC* images eliminate T_1 - and T_2 -weighting; voxel intensities reflect only the apparent diffusion.^{12,13} The *ADC* images are produced by fitting equation (2) to a series of two or more diffusion-weighted images of varying *b* value. The *ADC* images are then displayed with the voxel intensity related or scaled to the rate of diffusion. Visualization of cerebral details is sometimes easier from diffusion-weighted images, which are devoid of cerebrospinal fluid (CSF) hyperintensity because of the relatively faster apparent diffusion of water protons in CSF. In the corresponding *ADC* images, the pronounced CSF hyperintensity (reflecting faster apparent diffusion) can often limit the visualization of more subtle *ADC* differences in gray and white matter.

An appropriate example of ordered or anisotropic diffusion can be seen in proton diffusion-weighted images of fibrous vegetables or fruits. Apparent diffusion along the direction of

ordered fibers (measured by application of the diffusion-sensitizing gradient parallel to the long axis), renders the diffusion-weighted intravoxel intensity within the fibers hypointense, implying fast diffusion of water protons along the fibers (since rapid diffusion produces signal attenuation on diffusion-weighted images). Corresponding images acquired with the diffusion-sensitizing gradient perpendicular to the long axis of the fibers result in very hyperintense image intensity within the fibers, implying relatively slow proton diffusion (little echo loss) along this direction. The translational distances traveled by water protons perpendicular and parallel to fibrous matter during the MR observation time $(\Delta - \delta/3)$ of roughly 20–50 ms is estimated to be 5–13 μm (respectively). If water proton displacements in any given direction are significantly shorter than the statistical diameter of a structure of barriers along that direction, then little or no anisotropy will be observed. Anisotropy is apparent when the water protons within a voxel can sample the microenvironment adequately.

The rationale behind diffusional anisotropy in an ordered structure is that water protons within a matrix statistically prefer to move *along* ordered structures rather than *across* them (by the principle of least resistance). In other words, average proton displacements along the fibers are greater due to fewer barriers being present in this direction. Proton displacements are shorter across the fibers due to barriers presented by the very orientation of the fibers themselves. When the diffusion-sensitizing gradient direction coincides with the direction of least hindrance, the apparent diffusion appears greater and the observed *ADC* is larger.

Anisotropy of diffusion was first suggested as a possible explanation for the large regional differences in *in vivo* human white matter apparent diffusion coefficients by Thomsen et al.¹⁶ More recent descriptions of the existence of and characterization of *in vivo* anisotropy have subsequently appeared.^{10,17,18}

In axial and coronal diffusion-weighted images in animal models,¹⁰ the directional dependence of the white matter apparent diffusion is not observed in regions of gray matter. Within the corpus callosum, however, apparent diffusion can be as slow as $0.4 \pm 0.1 \times 10^{-5} \text{ cm}^2 \text{ s}^{-1}$ (across the short axis of the tract) and as high as $1.3 \pm 0.1 \times 10^{-5} \text{ cm}^2 \text{ s}^{-1}$ (along the long axis of the corpus callosum). This suggests faster proton diffusion in white matter along the direction of the long axis of the tract. From the observed image intensities and knowledge of the diffusion-sensitizing gradient direction, one can then ascertain the orientation of individual white matter tracts. The translational distances traveled by water protons perpendicular and parallel to the white matter orientation during $(\Delta - \delta/3) = 40$ ms can be estimated to be 6 and 11 μm respectively, suggesting that axonal diameters may be determinable from such measurements.

4 CLINICAL IMPLICATIONS

The *in vivo* directional diffusion-weighted images observed in human volunteers indicate that water proton diffusion anisotropy is best observed in the large diameter, fast-conducting motor and somatosensory nerve fibers (Figures 1–5). Significant anisotropy is observed in adult volunteers in all white matter tracts such as the corpus callosum, splenium, and in-

Figure 1 Axial, multislice diffusion-weighted images of a human volunteer acquired on a GE Signa at 1.5 T. Top row: minimal diffusion-weighting ($b = 12 \text{ s mm}^{-2}$). Second row: diffusion-sensitizing gradient applied along AP direction (up-down in images), $b = 512 \text{ s mm}^{-2}$. Third row: diffusion-sensitizing gradient applied along LR direction (left-right in images), $b = 512 \text{ s mm}^{-2}$. Bottom row: diffusion-sensitizing gradient applied along IS direction (through-plane in images), $b = 512 \text{ s mm}^{-2}$. All images were acquired with $TR = 2 \times$ cardiac cycle ($\sim 1500 \text{ ms}$), $TE = 102 \text{ ms}$ and 124 ms (second echo used for navigation), 1 NEX. Gradient durations $\delta = 45 \text{ ms}$, gradient separation $\Delta = 62 \text{ ms}$, gradient strengths $= 1 \text{ mT m}^{-1}$ (1 G cm^{-1}), FOV $= 24 \text{ cm}$, 128×256 matrix size, and scan times $= 4.3 \text{ min}$ for eight slices per TR . Navigation achieved by correction of navigational echo magnitude. CSF suppression not applied. All images are scaled except top row. On these images, containing T_1 -, T_2 -, proton density-, and diffusion-weighting, relative regions of hypointensity denote rapid apparent diffusion of protons. Regions of relative hyperintensity demarcate slower diffusion. Note little or no anisotropic effects in gray matter or lipids (which display very slow apparent diffusion). TR , repetition time; TE , echo time; NEX, average; FOV field of view

ternal capsules. In addition, myelinated tracts in spinal cord,¹⁰ optic (A. de Crespigny, unpublished data), and peripheral nerves²⁰ appear to be associated with significant anisotropic effects.

Several pioneering studies verifying white matter diffusional anisotropy in normal and abnormal human and neonate subjects have been presented.^{18,21–25} It has been shown that the newborn brain demonstrates isotropic diffusion of water molecules.^{22,23} As the brain matures, diffusion becomes anisotropic, being greater along the longitudinal axes of the major axonal bundles of the cerebral white matter than perpendicular to them.

This anisotropic ordering of water motion most likely occurs along the long axis of the individual neurofibrils as well as along or within the axons isolated by the myelin sheath. Studies indicate that the presence of myelin is not necessary for ordering of proton apparent diffusion since anisotropic proton mobility is seen in nerves lacking microtubules and fast axonal

Figure 2 Diffusion-weighted images chosen from one slice and taken from images in Figure 1. Top left: minimally diffusion-weighted; top right: diffusion-sensitizing gradient applied along AP direction (up-down in images), $b = 512 \text{ s mm}^{-2}$. Bottom left: diffusion-sensitizing gradient applied along LR direction (left-right in images), $b = 512 \text{ s mm}^{-2}$. Bottom right: diffusion-sensitizing gradient applied along IS direction (through-plane in images), $b = 512 \text{ s mm}^{-2}$. Note regional hypointensity in white matter tracts when applied diffusion-sensitizing gradient direction is parallel to white matter orientation. This is best seen in the image at top right, in the lower limbs of the splenium of the corpus callosum

transport.²⁶ It is reasonable to assume that the development of anisotropy is related to the development of myelin sheaths; however, the temporal evolution of anisotropy seems to precede that of myelination as described by most authors.²⁷ Additionally, diffusional anisotropy has been proved to occur in nonmyelinated nerve bundles.²⁶ Another possibility is that diffusion anisotropy develops in relation to the maturation of the microtubules, intraaxonal organelles that facilitate axonal transport.^{28,29} Thus, diffusion-weighted imaging (DWI) seems to be useful in the real time assessment of cerebral maturation.

The use of diffusion-weighted imaging for the determination of water proton apparent diffusion anisotropy may aid in the study of peripheral CNS tissues, which exhibit water proton diffusional anisotropy effects. One novel application, termed 'MR neurography',²⁰ can increase tissue contrast by using MR diffusion-weighting in a variety of directions to evaluate the diffusion tensor found in nerve tissue. An important adjunct to neurography is the use of fat saturation to reduce hyperintense artifacts due to the slow mobility of protons in lipid tissues and in the use of maximum intensity projection (MIP) methods to track nerve tissue in a MR angiography-like fashion.

Most clinical usage of diffusion-weighted MRI has been hampered by two significant problems, gradient strength and motion artifacts. Many clinical scanners possess gradients capable of strengths of no more than 10 mT m^{-1} (1 G cm^{-1}), limiting b values to roughly 300 s mm^{-2} along any given direction. These limitations typically require pulsing two or all

three gradients together for longer durations (with increases in TE to well over 100 ms) to push the b value to above roughly 500 s mm^{-2} , above which diffusion effects can be clearly seen above the inherent T_2 -weighting. This in turn limits the signal-to-noise ratio (SNR) and degrades image quality, an important factor in diffusion imaging since good diffusion-weighting will itself attenuate SNR exponentially.

More importantly, longer TE values lead to significant motional artifacts. Linear excursions of just a few millimeters can easily ruin images where diffusion-weighted tissue contrast arises from proton displacements on the order of microns. The solutions employed to date have included restraint of the head with rigid holders or vacuum cushions that seal the head in the coil. These are uncomfortable and are difficult to implement on

Figure 3 Series of three diffusion-weighted images were acquired at b values of 12, 350, and 512 s mm^{-2} to produce the pure diffusion (ADC) images shown here for the three gradient axes and for the same four slices shown in Figure 1. Top row: diffusion-sensitizing gradient applied along AP direction (up-down in images). Second row: diffusion-sensitizing gradient applied along LR direction (left-right in images). Third row: diffusion-sensitizing gradient applied along IS direction (through-plane in images). Note that regional hyperintensity on ADC images indicates rapid apparent diffusion. CSF hyperintensity is an example of fast apparent motion or diffusion, so much so that smaller variations in gray and white matter are masked out and difficult to appreciate. For this reason, diffusion-weighted or other image synthesis is needed. Fourth row: images of the 'trace' of the diffusion tensor determined for each of the slices shown in the top three rows. The trace of the tensor is essentially an average of the diffusion images from the three principal axes and is useful for removing orientation effects from diffusion-weighted or ADC images. The trace image is useful for discrimination of ADC alterations due to stroke or other cerebrovascular diseases,¹⁹ which is often difficult because of regional ADC differences due to white matter anisotropy. Bottom row: the synthesized 'standard deviation' images¹⁹ taken from the ADC images and the trace image. The SD image is essentially a pixel-by-pixel map of the deviations from the trace and can be very useful for the identification of white matter tracts and discrimination from stroke or regional gray matter

Figure 4 Enlargements from the ADC and anisotropy maps for one slice taken from the images shown in Figure 3. Top left: ADC image with diffusion-sensitizing gradient applied along AP direction (up-down in images). Top middle: ADC image with diffusion-sensitizing gradient applied along LR direction (left-right in images). Top right: ADC image with diffusion-sensitizing gradient applied along IS direction (through-plane in images). Bottom left: trace image. Bottom middle: standard deviation image

uncooperative patients, particularly when several images are required to map the apparent diffusion tensor or to synthesize ADC images.

Fast-scan and high-speed MRI capable of acquiring diffusion-weighted images in seconds or less requires typically large gradient strengths (not currently present on most clinical scanners) and has been limited to relatively low-resolution images which make proper visualization of the individual white matter tracts very difficult. The use of multiple shots or echo trains in

Figure 5 Enlargements of another slice from the image set in Figure 3; image layout is as for Figure 4. This slice clearly shows the genu of the corpus callosum in the center of the ADC images (top row), which is not seen in the trace image (bottom left) but stands out in the anisotropy image (bottom middle) due to the strong orientation effects of the corpus callosum

high-speed imaging to improve resolution or SNR will in turn render the images again sensitive to motional artifacts.

Phase navigation^{30,31} combined with a conventional single or multi echo imaging sequence has great potential for clinical application. It involves simple modifications of standard clinical pulse sequences using additional spin- or gradient-echoes acquired without phase encoding to map and correct each phase-encoded line or train of k -space. This can yield relatively motion-free images of excellent resolution with limited gradient strengths at the expense of conventional scan times. Uncooperative patients can create motion artifacts not easily correctable with linear phase navigation methods (A. de Crespigny, unpublished data). However, with motion correction or navigation, a multishot approach (using EPI, RARE, or spiral k -space coverage) could become the optimal apparent diffusion imaging technique, using conventional gradients to build resolution in much shorter scan times. This would be fast enough to acquire a series of images with increasing b value or varying gradient direction in order to generate an ADC or an orientation map.

Utilization of this unique MRI technique for determining the orientation of white matter through the measurement of water proton apparent diffusion has the potential greatly to improve our understanding and assessment of demyelination disorders, white matter infarcts with associated edema development,³² neoplasms involving white matter tracts, and of neonatal brain and spinal cord development. Significant proton anisotropic effects have also been observed in human arm muscle,³³ opening up the potential of using this technique to map performance or pathology. Finally, images devoid of white matter orientation effects can be synthesized by mapping the trace of the tensor enabling better visualization and earlier detection of ischemia in the CNS.¹⁹

1 INTRODUCTION

MRI studies of brain motion afford a unique window onto the mechanical homeostasis of the central nervous system (CNS). Velocity-sensitive MRI techniques may be based upon modulation of the magnitude or phase of the NMR image data, and have the capacity to detect the distributions of velocities, the displacements, or the material strainrates within the brain parenchyma. Having the capacity to resolve tissue displacements on the scale of micrometers, limited in practice by proton diffusion, NMR movies have mapped the physiological pulsation of the brain and spinal cord with the heartbeat and have measured brain parenchymal deformations due to everyday cranial accelerations. Clinical applications are projected to include the prediction of response to surgical treatment for a tethered spinal cord, and, potentially, the diagnosis of normal-pressure hydrocephalus. Brain motion studies will be of value in elucidating the mechanisms of CNS trauma of both exogenous and endogenous forms.

2 BRAIN MOTION

Physiological brain motion reflects the reaction of the brain parenchyma, spinal cord, and cerebrospinal fluid (CSF) to changes in arterial and venous pressure and volume with the cardiac pulse and respiration.¹ According to the Monroe-Kellie doctrine, cranial entry of an arterial blood volume bolus with each systole must be matched by an equal egress of blood, CSF, and brain parenchyma from this incompressible compartment.²⁻⁴ Ultimately, parenchymal egress is effected by the movement of the cervical cord caudally through the foramen magnum.

A detailed picture of the physiological brain motion has gradually emerged. DuBoulay postulated that CSF pulsation is pumped by the brain parenchyma, specifically the compression of the third ventricle by a medial motion of the thalami.⁵ MRI has since confirmed this and has been instrumental in the emergence of a more complete view. Anatomically, brain parenchymal pulsation may now be seen chiefly as a radial inflow of brain tissue inward and downward toward the foramen magnum: a herniation in miniature.⁶⁻¹⁰ For a superb treatment of multiaxial ciné velocity data, see Greitz et al.⁸ Most rapid motion is seen in the cervical cord and brain stem,

which descend at velocities as great as $5\text{--}10\text{ mm s}^{-1}$. By contrast, the cerebral mantle is almost immobile with respect to the calvarium. Velocities of intermediate size and complex 3D form are present in central deep gray and midbrain structures, among them the compressive motion of the thalami postulated by DuBoulay. Superimposed on the cardiac pulsation is a respiratory pulsation of a much smaller size.² Observations of brain parenchymal strain patterns (see Section 5.1) suggest that variation in vascular turgor, particularly of the large arteries, may influence the observed parenchymal motion. MRI measurement of CNS motion may be confounded by head movements of musculoskeletal or cardiac-ballistic origins.³

3 OVERVIEW OF MRI OF CNS MOTION

CNS motion has been assessed by a variety of NMR imaging techniques. The earliest MRI demonstration of CNS motion was offered by Feinberg and Mark, who in 1987 presented echocardiogram (ECG)-gated movies of Fourier velocity spectra along selected 1D lines within the head, as shown in Figure 1.^{6,11} (For pioneering work on Fourier transform imaging spectra, antecedent to the present techniques and to phase contrast MRA, see Moran.¹²) Later investigators have estimated mean velocity using reduced numbers of velocity phase encoding steps and increased spatial or temporal resolution in conventional 2D multishot MRI,¹³⁻¹⁵ echo planar MRI,¹⁰ and real-time 1D-selective line MRI ('M-mode' NMR).¹⁶ The technique of NMR 'interferography' of Hennig is a variant type of velocity encoding, based on a spatial modulation of local signal magnitude rather than phase.¹⁷ A quite different approach to CNS pulsation was taken by Lee, Wang, and Mezrich, who measured pulsatile changes in the volume of the lateral ventricles using conventional MRI.¹⁸

Figure 1 Fourier-encoded ciné velocity study for a selected line of tissue at the level of the foramen of Monroe. Cardiac gate delays from the R-wave are denoted. Cranio caudal velocities are depicted on the vertical axis, with single-pixel resolution of 0.4 mm s^{-1} . Line selection was performed using orthogonal slice selects. The basic downward "piston" motion of the midbrain is demonstrated. (Reproduced by permission from Feinberg and Mark⁶)

4 MOTION-SENSITIVE ECHO PLANAR MRI OF BRAIN MOTION

The displacements associated with brain motion range from a typical maximum of 1–2 mm in the cervical cord down to unmeasurably small values in the cerebral mantle. Consequently, brain motion justifies the highest feasible levels of motion sensitivity. MRI can achieve high velocity sensitivities by the method of magnetic gradient phase encoding, familiar in magnetic resonance angiography (MRA) and diffusion imaging and more recently in the imaging of myocardial motion.^{19,20} A pulsed gradient $\mathbf{G}$ is applied such that $\int_0^{\text{TE}} \mathbf{G}(t) dt = 0$ to induce a phase shift ϕ for velocity $\mathbf{V}$ of $\phi = \mathbf{k}_v \cdot \mathbf{V}$, where $\mathbf{k}_v = \int_0^{\text{TE}} \gamma \mathbf{G}(t) t dt$.

The velocity resolution of a phase-sensitive MRI experiment is approximately $\Delta \mathbf{V} = N/k_v S$, where N is the desired number of standard deviations of discrimination and S is the signal-to-noise ratio (SNR) of the MRI phase over the region in question, typically equal to π times the SNR of the MRI magnitude.²¹ If the velocity changes over time, the phase shift ϕ represents the time-average velocity weighted by the integral of the gradient: $E(T) = \int_0^T \mathbf{G}(t) dt$.¹⁰

4.1 Subtraction of Head Motion

Rigid motion of the brain and skull can be an important confounding factor in high-sensitivity studies of brain motion.¹⁰ Head motion is caused by cardiac pulsation, respiration, and involuntary activity of skeletal muscles seen even in cooperative subjects with good head fixation. Echo planar MRI has demonstrated that head motions of 1 mm s⁻¹ may occur even under relatively optimal conditions. Using ordinary means of head fixation, extrinsic skull motion and intrinsic CNS motion in the supratentorial region appear to be of similar magnitudes, but may be out of phase. In the cervical region, the craniocaudal motion of the cord is several-fold greater than extrinsic motion.

The effects of rigid head motion in studies of brain parenchyma motion can be conveniently removed by mathematical means.¹⁰ Using the fact that a rigid motion defines a linear function, velocities of the skull are measured, and brain motion due to this rigid motion estimated by linear interpolation (brain parenchymal strain rate may be corrected for rigid motion by subtracting from each component $\partial \mathbf{V}_i / \partial X_j$ times its mean value over the skull).²² When this rigid component of motion is subtracted out, the specific motion of the brain relative to the skull is revealed.

4.2 Limitations

MRI velocity sensitivity is ultimately limited by molecular diffusion and by the spatiotemporal characteristics of the motion pattern under study. Signal attenuation due to tissue water self-diffusion limits the intensities and durations of the gradient pulses that may be usefully applied. A gradient pulse of intensity G and duration δ establishes in the tissue parallel isophase planes of spatial period $\gamma G \delta$ diffusional attenuation becomes severe as the Einstein diffusion length $(2D\delta)^{1/2}$, where D is the diffusivity, approaches the isophase lamellar spacing.^{23–25}

A second limit to velocity sensitivity is imposed by signal attenuation due to velocity gradients within each voxel. Velocity gradients may result from rigid rotation or material shear. In the simplest case, velocity and phase are linear functions of position.

In this case, image magnitude will be attenuated by a Fourier coefficient of the spatial profile of the voxel.²² Typically, the voxel profile has the form of a rectangular function in the slice direction (z) and a sincfunction in each in-plane coordinate (x and y). Then the attenuation due to shear, A_{SH} , becomes simply

$$A_{\text{SH}} = \text{rect}(\partial \phi / \partial x) \text{rect}(\partial \phi / \partial y) \text{sinc}(\partial \phi / \partial z) \quad (1)$$

when the spatial coordinates (x, y, z) are expressed in units of pixel diameters, ϕ is in cycles and $\text{rect}(u) = 1$ if $|u| < \frac{1}{2}$, 0 otherwise. Equation (1) implies that attenuation due to in-plane velocity shear is all-or-none: 0% attenuation when $|\partial \phi / \partial x_i| < \frac{1}{2}$ cycle/pixel and 100% attenuation when $|\partial \phi / \partial x_i| > \frac{1}{2}$ cycle/pixel. No definite evidence of shear attenuation has to date been demonstrated in brain parenchyma, although such attenuation has been seen in the CSF in zones of high-shear such as the aqueduct.²⁶

4.3 Normal Pulsatile Brain Motion

Qualitatively, the intrinsic brain motion consists of a primary systolic downstroke of the brainstem, which moves like a plunger within the relatively fixed cerebral mantle, followed by a slower diastolic recovery toward the initial configuration. In synchrony with this axial motion, the thalami move inward bilaterally to compress the third ventricle. Anteroposterior velocities are typically less than 25% of maximum craniocaudal or mediolateral velocities.

Figure 2 shows the three components of intrinsic brain parenchyma velocity in axial slices in a normal volunteer. The slices are at the midventricular level, and ciné data were acquired with 50 ms temporal resolution. Gray scale images show the magnitude and mediolateral, craniocaudal, and anteroposterior velocity component images 100 ms after the ECG R-wave. The curves plot the velocity components as functions of time for the elliptical regions of interest indicated. The net craniocaudal displacement 100 ms after the R-wave is shown as a 3D surface in Figure 3. Craniocaudal velocity in a midline sagittal plane is shown in Figure 4. The velocity curves [Figure 2(b)] show a monophasic or biphasic motion burst 50–200 ms after the ECG R-wave, synchronous with the systolic arterial pulse wave arrival, and subsequently in diastole much smaller velocities of recovery (diastolic RMS velocity < 20% systolic). The velocity images demonstrate the rapid caudal descent and of central structures, and the medial compressive motion of the thalami; anteroposterior velocities are relatively small.

In normal volunteers, absolute CNS motion proves to be reproducible between heartbeats $\pm 15\%$ (SD). It follows that conventional multishot MRI with an ECG trigger would produce reasonably accurate maps of CNS motions.

4.4 Tethered Spinal Cord

Under normal conditions, the spinal cord participates in the pulsatile movement of the CNS, with significant vertical motion seen throughout cervical and upper thoracic levels. Physiological cord motion is normally rapid, with velocities of up to 10 mm s⁻¹, and may exhibit several cycles of damped oscillation, possibly related to elastic recoil of the dentate ligaments.²⁷

Figure 2(a)

Figure 2 (a) Images of intrinsic brain velocity components for axial slices at the midventricular level in a normal subject 100 ms after the ECG R-wave, the approximate moment of peak parenchymal pulsatile velocities. To the left are the magnitude images; to the right are the mediolateral, craniocaudal and anteroposterior velocity component images with scales. The craniocaudal velocity map shows the rapid central descent (dark gray to black), and the mediolateral image shows the rapid bilateral medial velocities of the thalami (white-black dipole). The bottom image shows the anteroposterior velocity component. (b) The velocity-time curves for the left thalamic ROI designated by the circle. Parenchymal velocities are highest between 50 and 200 ms after the ECG R-wave during cardiac systole; much slower velocities of parenchymal recovery are seen beyond about 200 ms after the R-wave, during diastole. ▲, cephalocaudal; ○, anteroposterior; ■, left-right

During normal development, the vertebral column undergoes greater craniocaudal growth than the spinal cord, and so the distal cord appears to ascend within the spinal canal. If the ascent of the cord is hindered by a mass, bone spur, or fibrous band, the cord may become stretched, which may lead by ischemia to symptoms of paresis, paresthesias, and loss of sphincter control. This syndrome is called the 'tethered cord',

and is treated surgically. Given the normal physiological motion of the cord, it is reasonable to inquire whether changes in the normal pattern of motion could be a diagnostic marker of tethering.

Investigators at The Johns Hopkins University School of Medicine and Georgetown have shown that motion of the cervical cord is a good predictor of clinical response to surgery

Figure 3 Net craniocaudal displacement of an axial slice 300 ms after the R-wave. Displacement is represented by the surface height, with a full scale of ± 3 mm. Image magnitude has been texture mapped onto the 3D surface. The predominant displacement is a monophasic downward movement of central structures; this figure corresponds to maximal displacement. Bidirectional CSF motion is seen in the horns of the lateral ventricles

Figure 4 Craniocaudal velocity in a midline sagittal slice. A magnitude image is at the top, and gray-coded images of craniocaudal velocity triggered at various times after the R-wave are shown at the bottom. Velocities in general increase with proximity to the foramen magnum, this downstroke systolic and is synchronous with the known systolic egress of CSF from the calvarium. Maximal velocities in the upper cervical cord are about 3 mm s^{-1} caudally

for a tethered spinal cord.^{7,13} If cord motion is normal, the patient is unlikely to benefit from surgical untethering, and an alternative etiology for neuropathic symptoms should be sought. Based on an experience of over 400 patients, MRI CNS motion studies are now standard at the Massachusetts General Hospital in cases of suspected tethering.

4.5 Normal-Pressure Hydrocephalus (NPH)

NPH is a syndrome of uncertain etiology whose classic form includes dementia, ataxic gait, and urinary incontinence.²⁸ Accurate diagnosis is imperative, as treatment can fully restore neurological function, whereas failure to treat may lead to progressive neurological dysfunction and death. At present, NPH diagnosis remains problematic, with no set of clinical or laboratory criteria clearly able to predict the individual response to CSF shunting.^{29,30}

Prompted by recognition of the abnormal CSF dynamics in NPH,^{29,31} MRI studies of brain motion in NPH have been undertaken. Wakhloo et al. found brain motion in NPH patients to have greater amplitude and complexity than in age-matched controls.³² This finding is particularly interesting because of

the support it lends to hypotheses linking the neurophysiology of the NPH syndrome with endogenous mechanical trauma.³³

5 NMR IMAGING OF PARENCHYMAL STRAIN RATES

Strain defines the degree of contraction and elongation at each point in a material during deformation. Velocity-sensitive NMR imaging can be used to reconstruct images of the distribution of physiological strain rates within tissues, including the myocardium and the brain parenchyma, as described here. By defining the pattern of tissue deformation at each location, strain imaging may shed light on both the mechanical causes and the specific neural effects of disorders of the mechanical homeostasis in the CNS. In an elastic material, strain is proportional to stress, which is the internal force per unit area, the constant of proportionality being the elasticity (in general, a fourth-order tensor).

Strain rates are described by a strain rate tensor $\mathbf{S}$ whose components S_{ij} are defined by the directional derivatives $\partial/\partial x_j$ of velocity components V_i according to

$$S_{ij} = 1/2 \left(\frac{\partial V_i}{\partial x_j} + \frac{\partial V_j}{\partial x_i} \right) \quad (2)$$

The rate of tissue elongation or contraction in the direction of a unit vector $\mathbf{v}$ is simply: $\mathbf{v}^T \cdot \mathbf{S} \cdot \mathbf{v}$. Measurement of the complete 3D strain rate tensor $\mathbf{S}$ by equation (2) requires acquisition of complete 3D spatial and velocity data. As such complete acquisitions have not yet been performed in the brain, images have been produced that reconstruct tensor components based upon one or two components of velocity.²⁰

To portray strain rate tensor fields usefully, novel display methods are needed. Let λ_i and $\mathbf{E}_i$ denote the eigenvalues and eigenvectors of the strain rate tensor, respectively, and let f be a positive constant such that $|f\lambda_i| \ll 1$ for all observed $\mathbf{S}$. Then the value of $\mathbf{S}$ at each location can be depicted by means of a small rhomboid whose axes are given by the four vectors

$$(1 \pm f\lambda_i)\mathbf{E}_i \quad (3)$$

Intuitively, this rhomboid shows the configuration of a unit square after $\mathbf{S}$ has acted upon it for a time equal to f . These rhomboids show the magnitude and direction of strain rate at each location; their long axes indicate the directions of most rapid stretch. Alternatively, a color code may be used to display the values of tensor invariants of the strain rate.

5.1 Normal Brain Parenchymal Strain Rates Due to Physiological Pulsation

Normal systolic parenchymal in-plane strain rate patterns are shown in Figure 5. In-plane (x and y) components of velocity were encoded in a gated ciné echo planar acquisition, and strain rates were computed according to equation (2). Data were acquired using a velocity sensitivity $|\mathbf{k}_v| = 3.7 \text{ rad s mm}^{-1}$ (gradient pulse intensity $G = 0.085 \text{ mT m}^{-1}$, duration $\delta = 35 \text{ ms}$, separation $\Delta = 40 \text{ ms}$). Given an MRI magnitude SNR per pixel of 25:1, this experiment should have the capacity to resolve velocity differences of 0.02 mm s^{-1} per pixel ($P < 0.05$). Defining the ‘strain rate’ sensitivity $\mathbf{k}_s$ so that the phase shift per pixel equals $\mathbf{k}_s \cdot \mathbf{S}$; then $\mathbf{k}_s = R\mathbf{k}_v$, where R refers to the dimensions of the voxel. In the experiments described, the strain sensitivity for in-plane strains is $|\mathbf{k}_s| = 3.7 \text{ rad s}^{-1} \text{ mm}^{-1}$ (for $3 \text{ mm} = 11 \text{ rad s}$). MRI motion sensitization in effect magnifies strain rates by the ratio of the strain rate sensitivity $|\mathbf{k}_s|$ to the motion observation period Δ ; here, $|\mathbf{k}_s|/\Delta = 275:1$.

The display shows a strain rate rhomboid, constructed according to equation (3), and uses color to depict the trace, $\text{Tr}(\mathbf{S}) = \lambda_1 + \lambda_2$. The trace represents the rate of compression or dilation of area within the 2D image plane. Because tissue is incompressible, in-plane area change implies compression or extension in the through-plane direction (i.e. $\text{Tr}(\mathbf{S}) + \partial V_z / \partial z = 0$).

Figure 5 Images of in-plane 2D strain rates of the brain parenchyma in a normal subject in (a) coronal-oblique and (b) sagittal planes 150 ms after the ECG R-wave, corresponding to the rapid parenchymal motion of cardiac systole. A rhomboid graphic at each pixel shows the magnitude and orientation of the 2D strain rate tensor $\mathbf{S}$ at that location [according to equation (3) with $f = 4 \text{ s}$]. Color indicates the rate of change of in-plane area, the trace of $\mathbf{S}$, with red denoting expansion [$\text{Tr}(\mathbf{S}) > 0$] and blue shrinkage [$\text{Tr}(\mathbf{S}) < 0$]. The predominant inflow of brain parenchyma toward the foramen magnum is striking in both image planes. The coronal slice shows prominent downward tissue elongation in and near the internal capsule; the sagittal slice shows downward and forward deformation of the cerebellum and midbrain, and vertical stretching of the upper cervical cord, also seen in the coronal image. Compression of the thalami upon the region of the third ventricle is evident in the strain rhomboids in the coronal image and is also evident in the sagittal image, where red hues of in-plane expansion near the third ventricle (at center) suggest compression in the through-plane direction

0). Color hue indicates the sign of $\text{Tr}(\mathbf{S})$ at each location, with red corresponding to positive and blue to negative. Color saturation is proportional to $|\text{Tr}(\mathbf{S})|$, with full saturation at $|\text{Tr}(\mathbf{S})| \geq 0.05 \text{ rad s}^{-1}$.

Figure 5 shows coronal and sagittal images of strain rate 150 ms after the ECG R-wave. Strain rate rhomboids demonstrate the predominant elongation of parenchyma toward the foramen magnum. In the coronal image, there is seen a dramatic elongation in the region of the upper cervical cord, internal capsule, and corona radiata; in the sagittal image such elongation is seen in the cerebellum and midbrain. Maximal strain rates in these zones are on the order of 0.1 rad s^{-1} . The red color in the region of the third ventricle in the sagittal image, denoting $\text{Tr}(\mathbf{S}) > 0$, demonstrates the through-plane compressive motion of the thalami in this zone. Small strain rates are seen in the cerebral mantle. Ciné velocity studies have shown, and strain rate ciné studies have confirmed, that motion in the territory of the basilar circulation precedes that in the middle cerebral territory cerebellar motion.⁹ Of interest, we see in the coronal image dilational strain patterns deep in the Sylvian fissures bilaterally. We can speculate that this reflects pulsatile motion of the middle cerebral vessels due to pulsatile turgor, the stiffening of the 'vascular endoskeleton'.³⁴

5.2 Brain Parenchymal Shear Due to Small Cranial Accelerations

The human brain is an organ uniquely vulnerable to acceleration injury. Acceleration injury is associated with a variety of clinical syndromes, including acute concussion syndromes of mild to profound severity and delayed effects, as in the dementia pugilistica or 'punch drunk' syndrome. An attractive unifying hypothesis is that these syndromes may be caused by acceleration-induced shear injury to deep cerebral white matter. This idea was advanced on theoretical grounds by Holburn, and soon received strong support in the experiments of Pudenz and Shelden, who, placing transparent windows into the skulls of monkeys, directly observed the swirling motion of the cerebral cortex due to cranial acceleration.^{35,36} Clinicopathological correlations in patients with severe concussion have demonstrated prominent damage to deep white matter tracts including the corpus callosum, cerebellar peduncles, and corticospinal tracts.³⁷ Particularly intriguing were the findings of hemorrhage at gray-white matter boundaries, suggesting elastic impedance mismatch as a cause of trauma. Similar lesion patterns have been seen in animal models of concussive nonpenetrating head injury.³⁸ These experiments, however, have become increasingly difficult to justify due to concerns for animal welfare.

MRI may afford the opportunity to characterize the response of the human brain to mild acceleration noninvasively, and, from this, perhaps to extrapolate the phenomenology of trauma. To investigate this, coronal images sensitive to anteroposterior velocity were acquired while a normal subject shook the head 'No' twice per second for 10 s. Contributions of rigid head motion were subtracted as described above, and data were processed to demonstrate the $\partial V_z / \partial x$ component of parenchymal shear, where z is the through-plane coordinate and x is the horizontal coordinate. Figure 6 shows intrinsic parenchymal strain rates at three points in the head shake cycle. Acceleration-induced shear rates in this experiment are at most 0.1 rad s^{-1} .

Figure 6 Brain parenchymal strain rates due to voluntary head shake. Images acquired during (a) clockwise cranial acceleration, (b) zero acceleration, and (c) counter-clockwise acceleration. The magnitude images are shown to the left and the strain rate images are to the right. The strain rate gray scale is proportional to $\partial V_z / \partial x$, where x is the horizontal and z is the through-plane direction. Locally increased $\partial V_z / \partial x$, indicative of localized rotation or shearing strain, are seen adjacent to the falx, in bilateral vertical bands deep to the temporal lobes, and at the spinomedullary junction where the brainstem seems to twist slowly upon the upper cervical cord

tion-induced shear rates in this experiment are at most 0.1 rad s^{-1} . This study demonstrates concentrations of strain adjacent to the falx, consistent with transmission of angular acceleration from the falx to the hemispheres. Shearing strain is seen to concentrate in parasagittal bands deep to the temporal lobes, and torsional strain to concentrate at the spinomedullary junction.

6 EFFECTS OF PARENCHYMA MOTION ON MRI OF PERFUSION AND DIFFUSION

Motion of the head and brain can interfere with studies of cerebral diffusion and cerebral function. Functional NMR studies of cerebral hemodynamic activation based on T_1 inflow or T_2^* deoxyhemoglobin effects must detect changes in signal magnitude of 1%.³⁹ These measurements, whether made with conventional or echo planar MRI, can be confounded by parenchymal inflow⁴⁰⁻⁴² related to cardiac and respiratory motions.^{43,44} Cerebral diffusion measurements are exquisitely motion-sensitive; when acquired using conventional multislice MRI, these studies are easily degraded by uncontrolled cerebral motion leading to phase inconsistency among Fourier data lines. This has been addressed by cardiac gating,⁴⁵ data post-processing,⁴⁶ compensation for measured motion using 'navigator pulses',⁴⁷ and by the adoption of single-shot acquisition techniques. Interestingly, whole-head motion has

overshadowed the effect of intrinsic brain motion in studies to date, suggesting the relative ineffectiveness of head fixation.

7 PROSPECTS

Motion-sensitive MRI opens a novel window onto the complex phenomena of brain parenchyma motion. This emerging picture of brain motion, however, represents only a first step of a program to understand the underlying biophysics of brain motion. At issue is the desire to know intracerebral distributions of mechanical stress. At a basic level, the distributions of stress may reveal the sites of action of the cardiovascular impulse and of resistance to it. Clinically, stress concentrations may account for the specificity of the neurological syndromes related to derangements of CNS dynamics (e.g. the relation of NPH to gait disturbance), and help predict the outcomes of intervention (e.g. how and when does fenestration of the optic nerve sheath alleviate the visual deficit of pseudotumor cerebrii). One promising avenue of study is exemplified by the work of Pelc and Enzmann, who have measured concurrent intracerebral volume changes of brain parenchyma, blood, and CSF,¹⁵ an important step toward the unification of brain motion with CSF dynamics in the spine and with the physiology of arterial pulse wave propagation.⁴⁸⁻⁵⁰

1 INTRODUCTION

The effects of diffusion on the NMR signal have been deeply analyzed and powerful diffusion measurement techniques using NMR have been extensively used in physics and chemistry. The recent application of such principles, coupled to NMR imaging (MRI) in the field of medical sciences, represents a spectacular and somewhat unpredicted development. The measurement of molecular displacements in biological tissues *in vivo* is of enormous interest in terms of its potential applications—from the determination of the molecular organization in tissues, to the emergency management of stroke patients, to the monitoring of laser surgery. MRI is the only means available today of approaching the molecular diffusion process *in vivo* noninvasively. In this article the basic principles of diffusion measurements made using NMR are presented, together with a description of the various methods that have been proposed for producing images of diffusion. Some technical considerations are discussed, followed by a description of the effects on diffusion measurements of the microdynamics and microstructure of biological tissues. Emphasis will be given to the difficulties encountered when implementing diffusion imaging, and the significance of diffusion measurements in biological tissues.

It has been proposed that, because of its relative safety, its high spatial and temporal resolution, its ability to acquire images in any orientation, and its greater availability compared to other modalities such as positron emission tomography (PET), MRI can be used to image perfusion. Two approaches have been developed that allow MRI to be used to image quantities related to perfusion. One approach mimics conventional nuclear medicine methods, but uses radioactively inert external tracers. The other approaches are more original and MRI specific, using blood directly as an endogenous natural tracer. Such methods offer new insights, for instance valuable information can be obtained by monitoring variations in blood oxygenation in human brain cortex during activation tasks. This article covers the physical principles and fields of applications of these techniques, both tracer and blood pool agent based approaches and methods specific to NMR where flowing blood is magnetically labeled. Finally, a large section of this article is devoted to the ‘blood oxygen level dependent’ (BOLD) contrast approach which has

resulted in the recent and fascinating incursion of MRI into the field of functional brain imaging. With MRI it is now possible to monitor completely noninvasively and with unmatched combined spatial and temporal resolution the activity of the brain during mental processes and the execution of cognitive tasks.

2 DIFFUSION MRI

2.1 Diffusion and NMR

The effect of diffusion on the NMR signal can be understood from the bipolar pulsed gradient spin echo experiment (echo time TE) suggested by Stejskal and Tanner¹ (Figure 1). The first gradient pulse induces a phase shift φ_1 of the spin transverse magnetization, which depends on the spin position z_1 :

$$\varphi_1 = \gamma G \delta z_1 \quad (1)$$

where γ is the gyromagnetic ratio, G is the gradient strength along the z axis, δ is the gradient duration. The time interval between the pulse onsets is denoted by Δ . After the 180° rf pulse, φ_1 is inverted to $-\varphi_1$. The second pulse will produce a phase shift φ_2 :

$$\varphi_2 = \gamma G \delta z_2 \quad (2)$$

where z_2 is the spin position during the second pulse. The net transverse magnetization is:

$$M_{xy}/M_0 = \exp[i(\varphi_2 - \varphi_1)] = \exp[i\gamma G \delta (z_2 - z_1)] \quad (3)$$

where all relaxation effects have been included in M_0 .

Obviously, for ‘static’ spins $z_1 = z_2$, so the bipolar gradient pair is easily evaluated. For ‘moving’ spins, however, there is a net dephasing which will depend on the spin history during the time interval Δ between the pulses. Indeed, we must now consider a population of spins, which may have different motion histories. If $P(z_2, z_1, \Delta) dz_2$ is the conditional

Figure 1 Stejskal and Tanner diffusion spin echo sequence. Gradients pulses G are separated by a time interval Δ ; their duration is δ

probability of finding a spin initially at z_1 between positions z_2 and $z_2 + dz_2$ after a time interval Δ , the amplitude attenuation is:

$$M_{xy}/M_0 = \int \exp[i\gamma G\delta(z_2 - z_1)] P(z_2, z_1, \Delta) dz_2 \quad (4)$$

In the case of the diffusion process, one has:

$$P(z_2, z_1, \Delta) = (4\pi\Delta D)^{-1/2} \exp[-(z_1 - z_2)^2/4\Delta D] \quad (5)$$

where D is the diffusion coefficient. Combining equations (4) and (5), the signal attenuation is:

$$M_{xy}/M_0 = \exp[-(\gamma G\delta)^2 \Delta D] \quad (6)$$

In practice, as δ is usually not negligible compared with Δ , movement during the application of the gradient pulses can no longer be neglected (see below). Also, the contribution of other gradient pulses, such as the imaging pulses, must be taken into account.² Solving the Bloch–Torrey equation,³ one obtains:

$$M_{xy}/M_0 = \exp\left(-\left\{\gamma^2 \int_0^{TE} \left[\int_0^t G(t') dt'\right]^2 dt\right\} D\right) \\ \equiv \exp(-b \cdot D) \quad (7)$$

This relationship is valid for any gradient pulse combination, provided the sign of G is inverted for all gradient pulses following the 180° pulse. This expression may become analytically complex when many gradient pulses are involved, as in MRI. Therefore, it is useful to characterize the sensitivity of MRI sequences to diffusion using the ‘gradient factor’ b .^{2,4} One must remember, however, that this equation is valid only for diffusion in an infinite and homogeneous medium. If diffusion is restricted or anisotropic, the signal attenuation must be calculated using a more general formalism based on diffusion tensors.⁵

2.2 The Different Approaches

Almost any NMR sequence can be designed to measure diffusion.

2.2.1 Constant Field Gradient Spin Echo Method

In the presence of a simple constant linear gradient G_0 , the echo attenuation is:^{6,7}

$$M(nTE)/M_0 = \exp(-\gamma^2 G_0^2 DTE^3/12n) \quad (8)$$

where n is the number of echoes in a multiple echo experiment. This simple approach is difficult to combine with NMR imaging because the presence of a constant gradient during the rf pulses of the imaging sequence severely impairs the selected slice profile. In addition, the relaxation time T_2 of the medium should not be too short, so that enough diffusion attenuation occurs during TE .

2.2.1.1 Bipolar Gradient Pulse Spin Echo Technique.

This technique, suggested by Stejskal and Tanner,¹ is by far the

most widely used sequence in NMR diffusion measurements. Taking into account spin diffusion during δ , equation (6) becomes:

$$M/M_0 = \exp[-\gamma^2 G^2 D\delta^2(\Delta - \delta/3)] \quad (9)$$

The diffusion time T_d can be formally defined as $(\Delta - \delta/3)$, but its physical significance is clear only when the gradient pulse duration δ is sufficiently short compared with Δ . Tissues with short T_2 values require short TE s which may not allow sufficiently long diffusion times to produce a large enough diffusion effect.

2.2.2 Stimulated Echo Technique

A stimulated echo is generated from a sequence consisting of three rf pulses separated by time intervals τ_1 and τ_2 . Gradient pulses must be inserted within the first and the third periods of the stimulated echo sequence (Figure 2). The diffusion time now includes τ_2 and can be much longer than with the spin echo sequence, because only longitudinal relaxation occurs during this time interval. The Stejskal–Tanner relationship [equation (9)] still applies, provided that the period τ_2 is included in Δ .⁸ The longer diffusion time is useful for studying very slow diffusion rates, or in compensating for the unavailability of large gradients.⁹ Unfortunately the signal is reduced by one-half compared with the spin echo signal.

2.2.3 Gradient Echo Technique

The effect of diffusion on the amplitude of a gradient echo formed by a bipolar gradient pulse pair of reversed polarity does not differ from that of a spin echo sequence.² However, if the gradient echo is part of a steady state free precession (SSFP) sequence, where some degree of phase coherence is propagated throughout successive cycles, multiple echo paths with different diffusion times and different diffusion weightings must be considered.¹⁰ In MRI, the

Figure 2 Diffusion-weighted stimulated echo sequence. The stimulated echo results from the spin excitation by three rf pulses separated by time intervals τ_1 and τ_2 . During τ_2 , relaxation is driven by T_1 and not T_2 . Diffusion effects can be enhanced by placing gradient pulses within the τ_1 periods, where transverse magnetization is sensitive to field inhomogeneities

contrast-enhanced (CE-fast) scheme has been proposed.^{11–13} Unfortunately, this sequence remains very sensitive to motion artifacts.¹⁴ Moreover, the effects of diffusion and relaxation are intermingled so that diffusion measurements are always contaminated to some degree by relaxation effects.¹⁵

2.2.4 Diffusion Measurements with B_1 Field Gradients

Diffusion measurements can also be achieved by means of the rf field (B_1) produced by an NMR rf coil oriented perpendicularly to the main transmit/receive NMR coil.^{16,17} With rf gradients, extremely short switching times can be achieved, since there are no eddy currents. Furthermore, substantial gradient strength may be produced from the rf transmitter, allowing the measurement of very low diffusion coefficients.

2.3 Combining Diffusion NMR with MRI

‘Diffusion-weighted’ images are obtained by inserting gradient pulses into any NMR imaging sequence. For quantification it is necessary to determine the degree of diffusion weighting, which is achieved by calculating the factor b [equation (7)] associated with the acquisition parameters. Without additional gradients, typical spin echo imaging sequences have intrinsically very low b values, typically less than 1 s mm^{-2} , so that diffusion effects are completely negligible (for water, $D = 2 \times 10^{-3} \text{ mm}^2 \text{ s}^{-1}$ at room temperature and the attenuation is less than 1%).^{2,18} When inserting gradient pulses for diffusion, however, the combination of the imaging and diffusion gradients produce cross terms in the b factors.^{2,19} These cross terms will depend on the time course of these gradient pulses and may be significant, so that the Stejskal–Tanner relation [equation (9)] is incorrect in most cases. Using the b factor values associated with each image, it is possible to compute diffusion images, i.e. images where the diffusion coefficient is determined for each pixel according to equation (7).^{2,4,9,18} The computation of such diffusion images is obtained by fitting the signal intensity of each pixel of a series of images differently sensitized to diffusion (i.e. with different b values) with equation (7) (Figure 3).

Using the spin echo sequence, it is possible to vary the strength or the duration of the diffusion-sensitizing gradients, or their direction, in order to enhance anisotropic diffusion effects.² The spin echo two-dimensional FT method is certainly the simplest to implement.^{4,18,20} Other sequences² that have been investigated are stimulated echo sequences; line-integral projection reconstruction; variants of the SSFP technique; ‘turbo’ sequences; and echo planar imaging.^{21,22} These schemes have been suggested to overcome, at least partly, some of the problems encountered with the spin echo two-dimensional FT method.

With echo planar imaging (EPI), the entire set of echoes needed to form an image is collected within a single acquisition period (single shot) of 25–100 ms. This is obtained by switching the echo signal formation in a train of gradient echoes, by means of a large gradient the polarity of which is very rapidly inverted as many times as is required to achieve the desired image resolution.²³ EPI may easily be sensitized to diffusion^{21,22} (Figure 4).

Figure 3 Plot of the logarithm of the signal intensity in brain white matter against the gradient factor b . The plot is linear, and the slope is equal to the diffusion coefficient ($D = 0.60 \pm 0.01 \times 10^{-3} \text{ mm}^2 \text{ s}^{-1}$)

Figure 4 Diffusion echo planar imaging sequence. The spin echo is split into a series of gradient echoes by quickly switching the readout gradient. Sensitization to diffusion of an echo planar imaging sequence can be easily achieved by additional gradient pulses (hatched boxes)

Sensitization consists of providing a pair of large compensated gradients for a period of time before rapid gradient switching and data acquisition. The refocusing may be achieved either by simply reversing the polarity of the gradient halfway through the period over which it is applied, or by inserting a 180° rf refocusing pulse at the midpoint without reversing the gradient polarity.

With EPI, motion artifacts are virtually eliminated. The accuracy on diffusion achieved with EPI is generally extremely good, as many images differently sensitized to diffusion can be generated due to the very short acquisition time (typically less than 100 ms). The EPI technique is the method of choice for in vivo diffusion imaging, although it is very vulnerable to susceptibility artifacts, which are responsible for image distortion or signal dropout, and to chemical shift artifacts which require efficient fat suppression. Diffusion-EPI has been successfully used to measure the diffusion of water in the human brain in volunteers and patients²¹ (Figure 5).

2.4 Experimental Considerations in Diffusion MRI

2.4.1 Gradient Requirements

Any mismatch between the diffusion sensitizing gradient pulses may cause artifactual signal losses, due to improper spin

Figure 5 Diffusion images calculated from a set of 16 diffusion-weighted coronal echo planar images of the brain of a normal volunteer. These are 64×64 pixel images with a field of view of 16 cm and thus an in-plane resolution of 2.5×2.5 mm. The section thickness was 10 mm. The diffusion gradients varied from 0 to 38 mT m^{-1} in the z direction, the duration of each lobe was 20 ms, and their separation was 6 ms ($b = 0$ to 872 s mm^{-2}). The acquisition time for each image was about 50 ms. Note that diffusion is highest in ventricular cavities containing cerebrospinal fluid (free water). Because of diffusion anisotropy, diffusion in corpus callosum is very low, while vertical frontal white matter tracts have higher diffusion (see Table 1)

rephasing. Two major sources of problems are commonly seen. One is gradient instability, which may arise when gradient amplifiers are driven hard for fast switching of large gradient intensities. Variations from shot to shot of the bipolar gradient balance results in widely distributed ghost artifacts. While such an artifact does not occur when a single-shot technique such as EPI is used, it is still essential to have high quality gradient amplifiers with some reserve capacity for accurate diffusion imaging. The second problem results from eddy currents generated mainly in the cryostat when switching rapidly large gradient pulses. Eddy currents may also be a major cause of gradient pulse mismatch, leading to signal loss. The best solution to this problem is undoubtedly to remove eddy currents at source by using actively shielded gradient coils, which have no fringe fields and therefore do not generate eddy currents. The use of a gradient coil of small dimensions, which remains at a fair distance from the magnet core and with which it is easier to generate large gradient amplitudes, is certainly an attractive alternative.²¹

2.4.2 Motion Artifacts

As the sequences used are deliberately sensitized to motion by the addition of large gradients, a major problem occurring with in vivo imaging of diffusion arises from irregular motion of the object. Artifacts result from discontinuities that occur between successive cycles of an imaging sequence. Results of such temporal incoherence are commonly visible as ‘ghosts’ along the phase-encoding direction. These ‘ghosts’ are particularly intense in the presence of the diffusion gradients and render the diffusion measurements meaningless. Cardiac gating has been used to mitigate this problem, but even this motion is not strictly cyclic. It is difficult to compensate diffusion imaging sequences for motion, since the use of successive bipolar gradient pulses considerably reduces the

value of the gradient factor b .² Chenevert et al.²⁴ have suggested eliminating any phase encoding from the acquisition by sacrificing one dimension of the image, which is then reduced to a single line. Ultimately, however, the best way to avoid motion artifacts is to use a single-shot technique, such as EPI, and to secure patients comfortably within the magnet using cushions or inflating devices.

2.5 Diffusion in Biological Systems

The diffusion coefficient of water in tissues has been found to be 2–10 times less than that of pure water (Table 1). This can be largely understood considering that water molecules are obliged to divert tortuously around obstructions presented by fibers, intracellular organelles, or macromolecules. Biological systems thus differ greatly from an ‘infinitely large medium’; they are very heterogeneous and made of multiple subcompartments (microstructure). Depending on the permeability of the barriers that limit these compartments, we have to consider exchanges and transport

Table 1 Diffusion Coefficients of Water in Human Brain^a

	$\times 10^3 \text{ mm}^2 \text{ s}^{-1}$
Cerebrospinal fluid	2.94 ± 0.05
Gray matter	0.76 ± 0.03
White matter	
Corpus callosum	0.22 ± 0.22
Axial fibers	1.07 ± 0.06
Transverse fibers	0.64 ± 0.05

^aMeasurements obtained in normal volunteers using a diffusion sensitized EPI sequence.²¹ Direction of fibers refers to z axis (direction of the diffusion sensitizing gradient pulses).

between them (microdynamics). A classical treatment of the NMR signal may not then reflect properly the tissue structure or properties. In these conditions diffusion coefficients may become meaningless if the measurement timescale or the measurement direction are not provided. The main difficulty is that the structure of the medium is generally unknown in detail.

2.5.1 Restricted Diffusion

Diffusion is restricted when boundaries in the medium prevent molecules from moving freely.^{2,25,26} When measurement times are very short, most molecules do not have enough time to reach boundaries, and so they behave as if diffusing freely. Once the diffusion time increases, an increasing fraction of molecules will strike the boundaries, and diffusion will deviate from the free behavior. The diffusion distance, calculated as for free diffusion using Einstein's relation $\langle \zeta^2 \rangle = 2DT_d$, shows a curvature and, finally, a levelling-off when the diffusion distance reaches the size of the restricting compartment. The effects of restriction, which depend on the shape of the restricting volumes and the types of restriction,² will thus appear in the NMR signal for diffusion times such that molecular displacements are of the order of the size of the restricting volumes.

When the restrictive barriers become permeable to diffusing molecules, the restricted diffusion pattern changes. An example has been given by Tanner²⁷ for the case of equally spaced, plane, and permeable barriers. When the diffusion time is increased, the apparent diffusion coefficient decreases, as expected for restricted diffusion, but saturates at a level which depends on the permeability constant.

2.5.2 Anisotropic Diffusion

Diffusion in tissues may also be anisotropic if hindrance or restriction is not the same for different directions of motion. The measured diffusion coefficient then varies according to the direction of measurement. Examples include muscle²⁸ and brain white matter (see Figure 6).²⁹

To consider anisotropy, the diffusion 'coefficient' must be replaced by a tensor, $\mathbf{D}$.^{1,5} The diagonal terms of the diffusion tensor D_{xx} , D_{yy} , and D_{zz} represent molecular mobility along the axes x , y , and z of the laboratory frame of reference, while the off-diagonal terms indicate how displacements are coupled in directions which are mutually perpendicular. The echo attenuation must be rewritten as:

$$M/M_0 = \exp \left(- \sum_{i=x,y,z} \sum_{j=x,y,z} b_{ij} D_{ij} \right) \quad (10)$$

where b_{ij} are components of a matrix $\mathbf{b}$ and D_{ij} are components of the diffusion tensor.⁵ Off-diagonal terms in the diffusion tensor may be important when the gradient directions do not coincide with the orthotropic directions of the tissue. The echo attenuation then depends on a combination of the diagonal and nondiagonal terms of the diffusion tensor.

The three orthotropic axes of the tissue coincide with the eigenvectors of $\mathbf{D}$. The diffusivities along these principal directions are the eigenvalues of $\mathbf{D}$. The main direction of the tissue, e.g. the fiber-tract direction for muscle or white

Figure 6 Diffusion image showing anisotropic diffusion in white matter. Excellent contrast is achieved, although T_1 and T_2 effects have been removed. Corpus callosum and temporal white matter fibers, which are horizontal, are dark. Vertical corona radiata frontal fibers and internal capsule fibers are bright. In brainstem, vertical fast-conducting motor and somatosensory tracts are also bright

matter, is given by the eigenvector with the largest principal diffusivity. Also associated with $\mathbf{D}$ are *scalar invariants*, such as $\text{Tr}(\mathbf{D})$, which are independent of the orientation of the sample with respect to the laboratory frame of reference; they depend only on the tissue microstructure.⁵

In white matter, the results of the measurements depend on the respective orientation of the myelin fiber tracts and the gradient direction at each different image location. Diffusion coefficients are significantly lower when the myelin fiber tracts are perpendicular to the direction of the magnetic field gradient used to measure molecular displacements (Figure 6). Considering that most NMR visible water is in the axons, a simple model would be to consider that water molecules are enclosed in the axonal spaces and that water diffusion outside the axons is prevented by the myelin sheath. Recent diffusion experiments have not been able to show complete restricted diffusion, since the diffusion distance increases linearly with the square root of the diffusion time, as for free diffusion³⁰ (Figure 7). The reduced value of the diffusion coefficient across myelin fibers can thus only reflect a decreased water mobility through the successive lipid layers.

2.5.3 Diffusion in Multiple Compartment Systems

Most diffusion measurements in biological tissues refer to an 'apparent' diffusion coefficient (ADC), and it is generally considered that diffusion in the measurement volume (the 'voxel', in imaging) has a unique diffusion coefficient:

$$D_a = \sum_i \rho_i D_i \quad (11)$$

This simplification may not always be legitimate, since most tissues are made of multiple subcompartments—at the least, intracellular and extracellular compartments. Assuming measurement times are short, so that diffusion is unrestricted

Figure 7 Plot of the diffusion distance against diffusion time in gray and white matter. The diffusion distance was obtained from the diffusion coefficient using Einstein's relationship. There is no leveling-off of the diffusion distance, suggesting that water diffusion is not completely restricted

in each subcompartment i , and there is no exchange, the signal attenuation is:

$$M/M_0 = \sum_i \rho_i \exp(-bD_i) \quad (12)$$

where ρ_i is the density of molecules diffusing in compartment i , and D_i is the associated diffusion coefficient. In this case, the 'apparent' diffusion coefficient that would be measured would depend on the range used for b and would not reflect properly the diffusion in the voxel. Measurements with low b values would then be more sensitive to fast diffusion components. The ideal approach would be to separate all subcompartments by fitting the data with a multiexponential decay. Unfortunately, the values for D_i are often low and not very different from each other, so that very large b values and very high signal-to-noise ratios would be required.

2.6 Conclusion

Diffusion thus appears to be a powerful source of contrast for tissue characterization or functional studies. It has been shown that there is no correlation between the diffusion coefficient and the relaxation times T_1 and T_2 . T_1 and T_2 may be normal or elevated in diseased states, while diffusion is lowered, as shown in early brain ischemia.³¹⁻³³ Other applications include temperature imaging, a technique based on the sensitivity of diffusion coefficients to temperature³⁴ (Figure 8). Temperature imaging is especially useful for monitoring interventional procedures.

3 PERFUSION MRI

Classical techniques used to measure and image perfusion can be split into three categories: methods based on diffusible tracers (Figure 1); methods based on intravascular tracers (blood pool tracers); and deposition techniques (microspheres) (Figure 9). Conventional perfusion measurement techniques based on radionuclide tracers have led to the identification

Figure 8 Comparison of temperature measurements using T_1 and diffusion MRI, and using probes (Luxtron) in a phantom. The accuracy was found to be 0.2°C with diffusion and 0.5°C with T_1

Figure 9 Principles of conventional perfusion measurements. Microspheres are particulates which, because of their size, are trapped at the entry of the capillary network; a count of their deposition pattern gives the flow rate. Diffusible tracers cross the capillary wall; their concentration in the tissue reflects blood flow. Intravascular tracers remain inside the capillary compartment and may be used to evaluate blood flow (under some assumptions)

of 'perfusion' with 'blood flow' in the tissue. However, perfusion has also often been used simply to denote the degree (density) of normal or abnormal microvasculature in a tissue as seen, for instance, with conventional catheter angiography.

3.1 Diffusible Tracers

Blood flow measurements using diffusible tracers were first introduced by Kety and Schmidt.³⁵ Blood flow can, in principle, be determined from two parameters: the arterial input $C_a(t)$, which is assumed to be uniform across all voxels, and the tissue tracer concentration, measured by means of the external imaging detector. The tracer tissue concentration at time T , $C_0(T)$, is related to the normalized arterial flow F (in mL min^{-1} per 100 g of tissue):

$$C_0(T) = (F/\lambda) \exp[-(F/\lambda)T] \int_0^T C_a(t) \exp[(F/\lambda)t] dt \quad (13)$$

where λ is the blood/tissue partition coefficient of the tracer.

With NMR, the tracers are nonproton nuclei, such as ^{19}F compounds, D_2O or H_2^{17}O ; so far these have been used in animal studies. Tissue concentration is determined from integrated spectral line areas with spectroscopy techniques or from pixel signal intensities with MRI methods after tracer has been administered, and the arterial input function is derived from blood samples or, in some cases, from monitoring the NMR signal in a peripheral artery (either on-line or off-line). In general, one has to deal with multiple compartment fitting, e.g. gray/white matter in the brain, signal contamination from surrounding muscles, and tracer recirculation.

^{19}F has a sensitivity and a resonant frequency which are close to those of the proton, and is thus easily observed by NMR. Most studies have used inhalation of inert Freon gases, such as FC22 (CHClF_2)³⁶ or FC23,^{37–39} which appear to be less toxic and induce fewer changes in brain physiology.

Deuterium is used as a tracer injected intraarterially in the form of deuterated water (D_2O), which quickly exchanges protons with the surrounding water to become HOD .⁴⁰ HOD behaves very similarly to normal water, and the potential toxicity is limited at low concentration. The low sensitivity of the nucleus and its short T_2 result in low signal-to-noise ratios.

^{17}O is a stable isotope of natural abundance of 0.0037%, is chemically equivalent to ^{16}O and has a very low toxicity, even at somewhat high concentrations. The current limitation to its use is its low availability and high cost. While the ^{17}O NMR signal has been observed directly,⁴¹ other workers have based their approach on the scalar coupling of ^{17}O which relaxes water protons efficiently.^{42,43} Much higher signal-to-noise ratios may thus be reached by observing ^{17}O water through proton–hydrogen MRI (Figure 10). ^{17}O may also be administered as H_2^{17}O and used similarly to H_2^{15}O with PET to evaluate perfusion, or as a gas to evaluate tissue oxygen extraction.⁴¹

3.2 ‘Blood Pool’ Agents

If a nondiffusible NMR paramagnetic agent, such as gadolinium diethylenetriaminepentaacetic acid (Gd-DTPA), is injected into the blood stream in the form of a bolus, the difference in magnetic susceptibility between the tissue and the blood where the contrast agent is compartmentalized results in internal magnetic field gradients, which extend far beyond the capillary limits and, therefore, represent a significant

Figure 10 Perfusion measurements based on relaxivity effects of $[\text{}^{17}\text{O}]\text{water}$. Cerebral blood flow (CBF) was found to increase with $p\text{CO}_2$, as expected (from ref. 43, with permission)

amplification effect over the simple relaxivity effect. These gradients are responsible for spin dephasing which leads to significant signal loss, especially with long echo time gradient echo sequences and high field strengths (Figure 11).

At ‘clinical’ concentrations, i.e. 0.1 mM kg^{-1} , the relationship between the tissue agent concentration and the NMR signal loss is experimentally linear:⁴⁴

$$\Delta R_2^* = \Delta(1/T_2^*) = k[\text{Gd}] \quad (14)$$

The constant k has been empirically determined in the brain, but potential variations between tissues, and especially abnormal tissues, remains an important issue.

Figure 11 Set of 16 echo planar images acquired after injection of a bolus of Gd-DTPA. Images were obtained at 1-s intervals. The transit of the contrast agent bolus through the brain capillaries produces a signal drop which lasts a few seconds. This drop is higher in gray matter than in white matter. The limited signal drop in the low grade astrocytoma suggests that the tumor has a low capillary density (blood volume)

Figure 12 Typical magnetic resonance signal time course study after injection of a bolus of Gd-DTPA in a patient with a high-grade glioma. Each curve corresponds to a given region of interest. The necrotic center of the tumor is completely avascularized. The tumor wall has a very large blood volume. Note that, due to the breakdown of the blood–brain barrier in the tumor, the contrast agent starts leaking inside the tumor, where T_1 effects (which counteract the susceptibility-related signal drop) may lead to underestimation of the blood volume SR2, area under first-pass curve [proportional to cerebral blood volume (CBV)].

As with other blood pool tracer approaches,⁴⁵ information on perfusion (i.e. blood flow, blood volume, or mean transit time) may, in theory, be derived from the tissue concentration–time curve. In practice, the local blood volume V derived from the magnetic resonance signal time course is proportional to the area (integral) under the tissue concentration–time curve:

$$V \propto F_a / Q \cdot \int S(t) dt \quad (15)$$

where Q is the total amount of tracer injected as a tight bolus, and F_a is the arterial blood flow. Only the relative blood volume is determined but, assuming the same blood comes from a common feeding artery, comparison can be made between different parts of the brain (Figure 12). Several difficulties have to be overcome when integrating the tissue concentration over time, such as the recirculation of the tracer.⁴⁶

As for the blood flow, in principle the recirculation of the tracer could be determined using the Stewart–Hamilton theorem:

$$F_a = V / \text{MTT} \quad (16)$$

where MTT is the mean transit time, i.e. the average time required by the tracer to pass through the tissue.⁴⁷ Ideally, the tracer should be introduced into the vascular compartment as an impulse bolus. In practice, the mean transit time could be determined by deconvolving the tissue concentration–time curve by the arterial input function obtained by monitoring the contrast agent concentration in a feeding artery using MRI (Figure 13).

Without the knowledge of the arterial input function, the area under the tissue tracer concentration–time course only gives the regional blood volume, and not blood flow.⁴⁸ This technique has been used clinically to produce semiquantitative maps of the regional cerebral volume, for instance in brain tumors (Figure 14). Under some circumstances, however, such as brain activation studies, blood volume evaluation may provide useful information on hemodynamic changes.⁴⁹

Figure 13 Diagram showing that the actual tissue concentration time course is the product of convolution of the tissue residue function and the arterial input function. (Adapted from Axel⁴⁵)

Figure 14 Blood volume map calculated from a set of echo planar images obtained during the transit of a bolus of Gd-DTPA. The tumor shows a rim with very high blood volume, while the necrotic center remains black. The blood volume is 2–4 times larger in gray matter than in white matter

3.3 Magnetic Labeling

3.3.1 Methods Based on Phase Shifts

Spins moving in the presence of a magnetic field gradient get out of phase. Depending on the capillary geometry and circulation conditions on the one hand, and the MRI acquisition parameters on the other, perfusion can be viewed

as a predominantly incoherent motion (intravoxel incoherent motion, IVIM)⁵⁰ or a predominantly coherent motion (intravoxel coherent motion, IVCM).⁵¹

3.3.1.1 IVIM. When the capillary bed is sufficiently tortuous, phase shifts of flowing spins are distributed within each voxel and result in signal attenuation. A simple approach considers microcirculation as a pseudodiffusion process.⁵⁰ The signal attenuation A depends then on a 'pseudodiffusion coefficient' D^* :

$$A \propto \exp(-bD^*) \quad (17)$$

$D^* = lv/6$, where l is the mean capillary segment length, and v is the average blood velocity; b is the gradient factor defined in equation (7). Pseudodiffusion has, in practice, to be separated from bulk water diffusion, which requires a high signal-to-noise ratio⁵² and hardware stability, given the very small blood volume fraction f in the brain (2–4%). The use of EPI allows one to obtain a large number of images in a short time and significantly reduces the occurrence of motion artifacts²¹ (Figure 15).

The IVIM parameters, f and D^* , may be related to actual perfusion in terms of blood flow F under some assumptions about capillary network organization:⁵³

$$F = 6f D^* / (\rho l_t l) \quad (18)$$

where ρ is tissue density and l_t is the average total capillary length (between the arteriole and the venule).

An interesting and successful approach is to use ^{19}F blood substitutes (perfluorocarbons), which remain in the vascular compartment.⁵⁴ Paramagnetic contrast agents may also be used to enhance signal from flowing blood.⁵⁵

3.3.1.2 IVCM. Considering now the coherent part of microscopic flow, even echo rephasing has been used in an attempt to observe perfusion in first and second echo difference images,⁵⁶ but variations in T_2 tend to mask the

effects of perfusion. A more powerful technique uses velocity compensation. It is possible to devise two sequences with the same echo time, one of which refocuses the effects of blood moving with constant velocity along capillaries ('flow compensated'), while the other gives an additional attenuation resulting from this motion. A difference image then highlights the effects of perfusion. This effect has been shown in a model of rat brain ischemia, where the perfusion deficit is clearly visible as the disappearance of the difference between the two images.⁵⁷ This technique, however, requires excellent hardware stability and high signal-to-noise ratio. The order of flow compensation by gradient nulling may be increased to take into consideration the tortuosity of the capillary network.

3.3.2 Arterial Water Spin Labeling

In the experiment proposed by Williams et al.⁵⁸ to look at brain perfusion, a series of rf inversion pulses is used to saturate continuously or invert spins of arterial blood water protons. The inflow of these inverted spins in the imaging volume results in a small signal loss S/S_0 , which depends on blood flow F :

$$F = (\lambda/T_{1\text{app}})(S/S_0 - 1)/2\alpha' \quad (19)$$

where λ is the brain/blood partition coefficient, α' is the effective degree of arterial inversion, and $T_{1\text{app}}$ is the apparent spin-lattice relaxation time in the presence of arterial inversion.

In practice, one has also to consider T_1 recovery of labeled flowing spins between the excitation and the detection slices, and cross relaxation between tissue water and macromolecules. A critical parameter is the degree of arterial spin labeling α' , which depends on the flow velocity and the technique used to label spins. Steady-state spin inversion has been successfully achieved using adiabatic fast passage (AFP) spin inversion.

Quantitative perfusion maps have been obtained with this technique at high magnetic fields in animals, which have a short distance between neck and brain. High magnetic fields may be required to achieve a sufficient signal-to-noise ratio and dispose of longer T_1 values. A variant of this technique is to invert or saturate spins in the imaged slice and to monitor entry of fresh spins. Results may not be quantitative, but variations in blood flow during brain activation tasks may be observed.⁵⁹

3.3.3 Blood Oxygenation Level Dependent (BOLD) Contrast

Although the approach based on Gd-DTPA was a significant breakthrough for functional brain imaging, it had several limitations, in particular the requirement to use an external contrast agent. The number of measurements is therefore limited (for instance, to one baseline and one activation image) and brain function cannot be evaluated in real time. Based on earlier works describing the magnetic properties of hemoglobin⁶⁰ and their effect on the magnetic resonance signal,⁶¹ it was recently suggested that deoxyhemoglobin (which is paramagnetic, although oxyhemoglobin is not) in red blood cells could be used as an endogenous contrast material.^{62,63} Kwong et al.,⁵⁹ closely followed by others,^{64,65} showed that MRI could be used to monitor in real time the local modulation of the level of blood oxygenation associated

Figure 15 Plot of the logarithm of the signal decay versus gradient b factor in the presence of IVIM (experiment carried out at 1.5 T on a 70-year-old human volunteer using IVIM EPI). A series of 16 differently diffusion-sensitized spin echo images was collected. For white matter, the plot follows a straight line, as expected for a pure diffusion process. The slope of the straight line gives the diffusion coefficient D . For gray matter, the plot clearly shows a curvature effect for low b values. This curvature has been ascribed to microcirculation effects. The straight line obtained for large b values gives the diffusion coefficient. The deviation from the diffusion asymptote, as measured at the intercept, gives the perfusion fraction f . D^* , blood velocity

Figure 16 Typical magnetic resonance (MR) signal time course study during brain activation by a visual stimulus using the BOLD method (1.5 T). Gradient echo EPI images were obtained at 3-s intervals. During the stimulus the MR signal increases. The amplitude of the signal change is usually small, but largely exceeds baseline fluctuations. After stimulation, the MR signal sometimes goes below baseline. There is a delay of several seconds between the beginning of the activation task and the MR signal change, due to the delayed hemodynamic response over the neuronal response

with brain activity on an individual basis, without the need for intersubject averaging.

During brain activation tasks, there is a large local increase in blood flow which overcomes a small increase in tissue oxygen uptake. There is, therefore, a surplus of oxyhemoglobin over deoxyhemoglobin, resulting in a reduction of the susceptibility effects and thus in increased MRI signal (Figure 16). The effect is usually small (a few per cent) and depends on the sequence parameters, the voxel size, and the field strength.^{66,67} Recent articles have demonstrated the tremendous potential of MRI to aid in our understanding of how the brain works, with unmatched combined spatial and temporal resolution^{68–71} (Figure 17).

Besides exploration of the normal brain, potential clinical applications include presurgical mapping,⁷² monitoring of recovery after stroke or head trauma, and monitoring the fate of neuropharmacological agents.⁷³ Presurgical mapping consists in functional evaluation of brain tissue to be removed or spared during surgery, for instance in cases of intractable complex partial seizures if language is to be spared during lobectomy. So far, hemispheric language dominance is determined from invasive and risky tests, such as the Wada test which is based on intracarotid amobarbital injection, and electrical cortical recording through electrodes positioned intraoperatively. It is clear that functional MRI (fMRI) language studies have the potential to replace such invasive tests.^{68,74} On the other hand, fMRI could also be used to visualize epileptic foci with, or even without, associated clinical seizure. The use of fMRI for monitoring of functional recovery after stroke or head trauma appears especially important for patients with hemiplegia or aphasia. Studies may be repeated at will on individuals during the recovery period without concerns about irradiation.

MRI could also be used to visualize regions of the brain where receptors have been activated or inhibited by neuropharmacological agents through effects on blood flow and blood oxygenation, as we recently suggested using

Figure 17 Activation map of the visual cortex. Activation maps can be calculated by identifying pixels where significant magnetic resonance signal change occurred during stimulation. The degree of activation is shown using a color scale. The raw BOLD images were obtained using a spoiled-GRASS gradient echo (SPGR) sequence with a spatial resolution of $0.8 \text{ mm} \times 1.6 \text{ mm}$. The activation map is overlaid on a high resolution anatomical image to show the exact location of activation

neurochemical activation by arecholine in monkey brain.⁷³ Also, the modulation by such drugs of the response of the brain to specific stimuli or cognitive tasks could be evaluated.

There are, of course, some limitations when using fMRI. Patient cooperation is particularly necessary. Not only is their active participation required for the activation tasks, but they are also required to stay absolutely immobile during scanning in order to avoid misregistration artifacts. Registration algorithms are being evaluated, as well as sophisticated statistical analysis packages. Another concern regards the size of the vessels (veinules or feeding arteries) responsible for the effect. If the vessels are not small enough, they may correspond to a fairly large territory, so that the area of activation may differ from the location where activation is seen on the images.

3.4 Conclusion

MRI appears to be a very promising imaging modality for looking at microcirculation and perfusion. Compared with other approaches, MRI may provide images of high temporal and spatial resolution totally noninvasively. However, today, methods which give the best spatial and/or temporal resolution are not always quantitative, at least in terms of blood flow or other physiological parameters, often due to the lack of an adequate model. On the other hand, there are techniques, most of them using the basic principles of more conventional methods, which are potentially quantitative, but remain difficult to implement and give images with limited spatial and/or temporal resolution. It is likely that progress

will be made in both directions, so that physiologists and clinicians will soon have available to them methods which give quantitative information on perfusion with unmatched spatial and temporal resolution.

Diffusion: Clinical Utility of MRI Studies

Ole Henriksen

Danish Research Center of Magnetic Resonance, Hvidovre University Hospital, Denmark

1 INTRODUCTION

Tissue characterization by MRI has been a subject of great interest because the multiparameter dependence of the MRI signal makes it possible to improve the differentiation between various pathologies in vivo, which may lead to an improved specificity of clinical MRI investigations. So far, these approaches have mostly been based on signal contrast behavior due to differences in proton densities, and T_1 and T_2 relaxation behavior between different tissue types. In recent years, methods for studying diffusion processes in vivo by means of MRI have been developed, and possible clinical applications are currently under investigation. The studies published so far have mostly been directed to imaging of diffusion processes of water in the human brain. The results are very promising with respect to future clinical utility. These studies will be described in this article, outlining possible major areas of application for diffusion studies in clinical practice.

2 MRI MEASUREMENTS OF WATER DIFFUSION IN BIOLOGICAL TISSUES IN VIVO

A detailed description of the factors which influence the diffusion of water molecules in biological tissues is given in other articles (see the list of related articles). Only those aspects relevant for the interpretation of clinical in vivo diffusion studies will therefore be considered here.

2.1 The Concept of Restricted Diffusion

Translational molecular diffusion processes are a phenomenon in which molecules in a fluid of infinite extent move along random paths, colliding with and moving past each other. Diffusion can be described in statistical terms. The diffusion coefficient, D , describes the mobility at the molecular level, and has the unit of length squared per unit of time. D is specific for a given molecule, and varies with viscosity and temperature. For the free diffusion of water molecules in water the diffusion coefficient D is approximately $3 \times 10^{-9} \text{ m}^2 \text{ s}^{-2}$ at 37°C . If the diffusion coefficient of water in a given tissue is less than this value at 37°C , and it varies with the diffusion time, the diffusion is said to be restricted, and depends on a number of factors related to the microstructure of the tissue in question, which will be described briefly below.

The water diffusion in the cytosol may be hindered by the presence of barriers such as cell membranes, intracellular organelles, the presence of macromolecules, electrical charges, etc. The consequence is that the diffusion path of the water molecule becomes geometry-dependent, and the concept of a diffusion coefficient depending only on the properties of the diffusion medium breaks down. The practical consequence is that the diffusion coefficients obtained in MRI studies also include prolonged diffusion paths encountering such barriers (tortuosity), and they should thus be regarded as 'apparent diffusion coefficients', and are denoted D^* in the following discussion. The signal contrast in diffusion-weighted imaging depends on the design of the pulse sequence because D^* depends on the time (diffusion time) in which the diffusion processes influence the signal obtained by diffusion-sensitized pulse sequences. If the diffusion time is very short, the probability that a water molecule meets a barrier is low compared with that of diffusion over a longer period of time. Thus, D^* decreases monotonically from values close to D for short diffusion times to a constant smaller value as the diffusion time is extended to very long periods.

The fractional signal attenuation, A , due to diffusion in a given time, Δ , in pulsed gradient experiments, neglecting the small effects of the imaging gradients, can be written as

$$A = \exp[-bD^*(\Delta)] \quad (1)$$

where b is the diffusion attenuation factor in units of time per length squared [equal to $\gamma^2 G^2 \delta^2 (\Delta - \delta/3)$] and $D^*(\Delta)$ is the apparent diffusion coefficient at the diffusion time, Δ (δ is the effective gradient duration and Δ is the time between the leading edges of the pulses). Thus, in images displaying D^* , tissues with high D^* will appear with a high signal intensity. In diffusion-weighted images the situation is the opposite, as tissues with high D^* values tend to appear with low signal intensity, but the interpretation is more difficult because the signal will also be influenced by T_1 - and T_2 -weighting factors. Even though the D^* in cerebrospinal fluid (CSF) is very high and equals D , the signal appears bright in diffusion-weighted images using a diffusion-sensitized spin echo sequence because the T_2 of CSF is very long compared with that of the brain tissue.

2.2 Sources of Errors

Apart from imperfections in the MRI equipment, macroscopic movements are a main source of error in diffusion studies in vivo. Patient movements may be minimized by careful fixation, but one still has to take physiological movements induced by arterial pulsation, respiration, etc., into account. Studies of brain motion using the phase contrast method¹ have indicated an average velocity of about 0.5 mm s^{-1} during the cardiac cycle, corresponding to distances of at least $10 \mu\text{m}$ in 20ms, which are very similar to the expected values for the apparent average diffusion distance with Δ of 20 ms.

Cardiac and respiratory synchronization and compensation for first order bulk movements by gradient moment nulling techniques reduce the movement problems considerably when spin echo sequences are used.^{2,3} Another way is to use single-shot sequences with very short imaging times.³

Table 1 Clinical MRI studies of diffusion in human brain tissues

Tissue	Apparent diffusion coefficient $D^*/(10^{-9} \text{ m}^2 \text{ s}^{-1})$	References
CSF	2.9–3.5	3,4,5,6
White matter	0.2–1.7	4,7,10,11
Perpendicular	0.2–0.9	2,7
Parallel	0.8–1.5	2,7
Gray matter	0.7–2.3	3,6,8,9,10

3 CLINICAL MRI STUDIES OF DIFFUSION IN BRAIN

3.1 Normal Subjects

So far the vast majority of in vivo diffusion studies applied to human beings have been carried out on the brain. The reasons are that the brain movements are small, and the relatively long T_2 values of brain tissue make it possible to achieve a reasonable signal-to-noise ratio in high-resolution images (voxel size 8 mm^3). Relatively few studies where quantitative measurements of the apparent diffusion coefficient have been performed in healthy humans have been published so far. The results are summarized in Table 1. The main findings are that the apparent diffusion coefficient is reduced in gray and white matter compared with the diffusion coefficient of water molecules in water at 37°C (Figure 1). Studies of white matter

indicate that the diffusion is anisotropic, as the apparent diffusion coefficient is smaller for diffusion perpendicular to than parallel to the direction of the axons.¹¹ Another important finding is that the diffusion appears to be restricted in white matter perpendicular to the direction of the nerve fibers as D^* decreases for diffusion times above 26 ms, which corresponds to an average diffusion distance of about $4\text{--}5 \mu\text{m}$.⁵ No sign of restricted diffusion is seen in the direction of the fibers up to distances of $9 \mu\text{m}$.⁵ The same seems to be true for gray matter.⁵ The apparent diffusion coefficients obtained in CSF may be regarded as a kind of internal control of the validity of the quantitative measurements, since the expected values should be equal to the diffusion coefficient of water molecules in water at 37°C ($D = 3 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$). In the early study of Thomsen et al.,⁸ D^* in CSF is higher than the expected value of free diffusion in water, indicating that bulk movements contributed to the measurement. In a later study where compensation for movements of constant velocity is incorporated, D^* in CSF corresponds to the expected value.²

3.1.1 Age Dependency

Gideon et al.⁶ have observed that the apparent diffusion coefficient for water in deep white matter increases with age from $0.7 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$ (age ~20 years) to approximately $1.0 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$ (age 60–75 years), using a flow-compensated, diffusion-sensitized spin echo sequence with a diffusion time of 19 ms (Figure 2). This relationship between water diffusion and age has not been seen in gray matter.⁶ Measurements on

Figure 1 Images of the calculated apparent diffusion coefficient of water in the brain of (a) an adult healthy volunteer and of (b) a premature neonate (gestational age 33 weeks). The calculated images are based on diffusion-weighted spin echo sequences with compensation for first-order bulk movements. ECG triggering was performed as well. The color scale shown to the right of the images is linear, corresponding to $D^* = 0$ (magenta) to $D^* = 3.5 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$ (red) which corresponds to the free diffusion coefficient of water in water at 37°C . The voxel size is $1 \times 1 \times 8 \text{ mm}^3$. Note the relatively low D^* in white matter perpendicular to the fiber direction in the adult brain and that D^* is considerably less than in the CSF, which corresponds to the free diffusion of water molecules in water. In contrast to the adult brain, the D^* in white matter is higher than in gray matter in the neonatal premature brain

Figure 2 D^* of water in periventricular white matter of healthy subjects plotted against age. Regression analysis shows a significant correlation between D^* and age. (Adapted from Gideon et al.⁶)

neonates and small infants suggest that the degree of water diffusion anisotropy in frontal white matter and optic radiation is less in neonates than in young adults.¹² No clear difference is seen between the neonates and adults when D^* is measured parallel to the direction of the fibers.¹²

3.1.2 Diffusion-weighted Imaging

The studies mentioned so far in which the apparent water diffusion in human brain has been estimated in quantitative terms indicate that the water diffusion in white matter is restricted and there is an appreciable degree of anisotropy. The possible mechanisms underlying the diffusion anisotropy in brain white matter is discussed in *Anisotropically Restricted Diffusion in MRI*, but the observations in neonates¹² suggest that the myelin sheaths may at least be partly responsible. The practical consequence is that anisotropically restricted diffusion creates a signal contrast between nerve fiber bundles running in different directions in relation to those of the diffusion-sensitizing gradients. This has been shown in a number of studies where major ascending and descending projection tracts are visualized.^{5,13} It should be recalled that nerve fibers running perpendicular appear brighter than those running in parallel with the direction of the diffusion-sensitizing gradients.

3.2 Brain Pathologies

3.2.1 Brain Ischemia

A number of animal studies show that the apparent diffusion of water is reduced in experimentally induced ischemic areas of the brain.^{14–16} These alterations seem to be detectable within the first half hour after the onset of brain ischemia, and occur a long time before changes are detectable in T_2 -weighted images.^{15,17} In diffusion-weighted images, focal ischemic areas appear brighter than normal brain tissue in a gray–white scale, because the smaller apparent diffusion coefficient of water causes less reduction of the signal due to diffusion processes. The animal studies also indicate good agreement between the anatomical spreading of focal brain ischemia as visualized by diffusion-weighted imaging, perfusion-related imaging of the passage of a gadolinium compound (input function is not taken into account), and histological evaluation based on staining

with Evans blue.^{14,17} Diffusion-weighted imaging of photochemically induced ischemia in rat brain shows hyperintense signals corresponding to the ischemic area on the first day. During the following days the signal intensity fades, indicating that the diffusion of water becomes less impeded in the subacute stage.¹⁶

Taken together, the animal studies mentioned above clearly demonstrate that the apparent diffusion of water is reduced in ischemic brain tissue and that these alterations occur in the very early phase. The reason for the impeded diffusion of water is unclear at present. It cannot be explained by a decrease in tissue temperature because this has to drop about 10°C in order to explain the observed decrease in the apparent diffusion coefficient of water of about 30%. It seems to be associated with energy failure secondary to severe ischemia.¹⁸ The impediment of diffusion probably reflects alterations of the water balance between tissue compartments, swelling of membranes, and accumulation of macromolecules.

Only a few studies of water diffusion in the brain of stroke patients have been published. As early as 1987 Thomsen et al.⁸ had presented evidence suggesting that the apparent diffusion coefficient of water is reduced in subacute brain infarcts. Warach et al.¹⁹ have studied 32 patients with stroke using a high-speed diffusion-weighted stimulated echo sequence (turbo-STEAM). The time after the onset of symptoms ranged between 1 h and about 4 months. Diffusion-weighted images confirm the results of the animal studies described above, as a hyperintense signal is seen in the ischemic area, and these changes can be seen in the very acute stage where no changes are seen in T_2 -weighted images (Figure 3). In accordance with this, parametric images of the calculated apparent diffusion coefficient of water show that this is reduced compared with the contralateral side in the acute and subacute stages, whereas the apparent diffusion coefficient in infarcted tissue is increased in the chronic stage (Figure 4). The absolute values of D^* may have been influenced as bulk movements due to gross head movements, brain movements caused by arterial pulsation,^{1,2,20} and respiration may not have been sufficiently controlled. However, another study using a diffusion-sensitized spin echo pulse sequence and cardiac triggering also suggests a reduced apparent diffusion of water in ischemic areas following acute stroke.²⁰ These results show a considerable interindividual variation, and they do not indicate a significant correlation between D^* and the duration of ischemia.

Taken together, the experimental animal and human studies have established that the apparent diffusion coefficient of water is reduced in brain tissue subjected to severe acute ischemia, and that these alterations can be visualized at a very early stage. The evidence obtained suggests that the apparent water diffusion coefficient increases within the lesion to supranormal values in the chronic stage of stroke. As mentioned before, the exact pathophysiological events underlying these observations are still poorly understood. When the diffusion values obtained in these often elderly patients are compared with those obtained in healthy volunteers, the latter should be carefully age matched because the apparent diffusion coefficients in white matter have been shown to increase with age⁶ (cf Figure 2). Further studies on anisotropy as well as on the relationship between water diffusion characteristics and regional cerebral perfusion are warranted in order to obtain a better understanding of the underlying pathophysiological mechanisms in acute

Figure 3 T_2 -weighted (left) and corresponding diffusion-weighted (right) images obtained (a, b) 105 min, (c, d) 13 h, (e, f) 9 days after an acute stroke incident. Note that the ischemic tissue located in the left hemisphere can already be clearly visualized approximately 1.5 h after the clinical attack, where no changes are seen in the T_2 -weighted image. (Reproduced by permission from Warach et al.¹⁹)

Figure 4 Calculated apparent diffusion coefficients (ADC) ratios of water in ischemic and contralateral nonischemic brain tissue plotted against time after a stroke incident. Note that the ratios seem to increase from values <1 in the acute and subacute stages to values >1 in the chronic stage. (Adapted from Warach et al.¹⁹)

cerebral ischemia, and to be able to evaluate the prognostic information in diffusion-weighted images of brain ischemia with respect to tissue survival.

3.2.2 White Matter Disorders

Quantitative water diffusion studies indicate that the apparent diffusion coefficient is increased in *multiple sclerosis lesions* as compared with healthy age-matched volunteers,²¹ in agreement with preliminary results published by Larsson et al.,²² (Figure 5). Possible influences by movement due to brain pulsation and flow phenomena have been taken into account

by using a flow refocusing sequence and cardiac triggering. It is of interest that the apparent diffusion coefficient is higher in acute lesions than in chronic but stable lesions, and that there is a significant increase in D^* in apparently normal white matter in the conventional spin echo images²¹ (Figure 6). Finally, no relationship between the apparent diffusion coefficient and the T_2 relaxation rate measured by means of a multi-spin echo technique is seen, stressing that these phenomena depend on different mechanisms.²¹ Diffusion-weighted imaging of a patient with chronic multiple sclerosis shows a high signal in the lesion compared with apparently normal white matter.²¹ Since D^* of water is increased, as shown by Christiansen et al.,²¹ a low signal should be expected in the diffusion-weighted images. The most likely reason for this is that the T_2 weighting dominates compared with the effect of increased diffusion in lesions with high T_2 values when pulsed gradient, diffusion-sensitized spin echo pulse sequences are used.

Even though our experience is relatively limited, the results obtained so far are promising with respect to differentiation between acute and chronic multiple sclerosis lesions.²¹ The higher D^* value in acute than in chronic lesions may reflect an increase in water content due to edema and demyelination in acute lesions, whereas gliosis dominates in the chronic stage.

To what extent diffusion studies may contribute to the differential diagnosis between lesions due to multiple sclerosis and other diseases including, for example, subcortical infarcts and viral infections, is still too early to say, as systematic comparative diffusion studies are still lacking. A single case study suggests that diffusion-weighted imaging may give further information in patients with *progressive multifocal leukoencephalopathy*.¹³

Figure 5 (a) T_2 -weighted and (b) calculated apparent water diffusion coefficient images obtained in a patient with an acute attack of multiple sclerosis. The color scale shown to the right is similar to that described for Figure 1. Note the increase in diffusion corresponding to the acute lesion seen at the left posterior horn of the lateral ventricles. There also seems to be an increased diffusion in the apparently normal periventricular white matter. (Reproduced by permission from Christiansen et al.²¹)

Figure 6 Apparent diffusion coefficient of water in white matter obtained in age-matched controls (left) and patients with chronic and acute multiple sclerosis lesions. Note that the average diffusion coefficient obtained in apparently normal white matter of multiple sclerosis patients is significantly increased compared with the control group. (Adapted from Christiansen et al.²¹)

3.2.3 Intracranial Tumors

Only a few studies on a limited number of patients with intracranial tumors have been reported so far.^{5,23,24} The findings suggest both an increase and decrease in D^* within, as well as between, tumors compared with normal brain tissue

Figure 7 (a) T_2 -weighted and (b) calculated apparent water diffusion coefficient images, obtained from a patient with a cystic astrocytoma. Note that D^* in the central part of the tumor is close to the free diffusion of water in water, indicating a cystic component of the lesion containing free fluid

(Figure 7). The increase in D^* is most prominent in cystic parts of the tumor approaching that of CSF and water. Diffusion measurements seem to make it possible to differentiate between solid tumor tissue and cystic lesions having the same appearance on conventional T_1 - and T_2 -weighted images due to a high content of paramagnetic protein. In the

latter case, diffusion studies will reveal D^* values corresponding to cyst fluid.²⁵ Diffusion studies may also improve the assessment of the delineation between epidermoid tumor and adjacent CSF.²³

The extent to which diffusion studies may improve the tissue characterization of solid brain tumors is as yet unclear. Another important clinical aspect is whether diffusion studies allow differentiation between solid tumor and surrounding edema. Anecdotal evidence suggests that the signals from presumed edema in diffusion-weighted images are isointense with the solid tumor components but the edema may be associated with a higher degree of diffusion anisotropy.¹³ It is, however, much too early to draw any definite conclusions.

3.2.4 Disturbances in CSF Hydrodynamics

Preliminary studies indicate that the apparent diffusion coefficient of water is significantly higher in white as well as gray matter of patients with *normal-pressure hydrocephalus* than in a group of healthy age-matched controls²⁶ (Figure 8). Surprisingly, the diffusion coefficients in the CSF of the patients seem also to be higher than in the controls, even though the diffusion-sensitive pulse sequences were compensated for first-order motion, and ECG triggering was performed. Since pulsatile motion of CSF is increased in these patients,²⁷ a higher degree of complex flow patterns may have contributed to the signal loss. This may explain the apparent elevation of the diffusion coefficients in CSF of patients with normal-pressure hydrocephalus. Examination of two patients with *high-pressure hydrocephalus* also suggests a higher apparent diffusion coefficients in both white and gray matter compared with normal subjects.²⁶ The increase in the apparent diffusion of water in brain white matter of patients with normal-pressure hydro-

cephalus may reflect the loss of myelin sheaths, especially in the periventricular regions.

Soelberg Sørensen et al.²⁸ have observed a pronounced increase in the apparent diffusion coefficient of water in patients with *benign intracranial hypertension* or *pseudotumor cerebri*. The alterations in water diffusion are most pronounced in the periventricular white matter. In some cases the calculated apparent diffusion coefficient exceeds that of free diffusion of water in water, indicating that the obtained diffusion values may to some extent have been influenced by pulsatile movements of the brain as well as by convective water movements in the brain tissue. In a later study where first order movement was corrected for in the pulse sequence, Gideon et al.²⁶ confirm that the apparent diffusion is increased in periventricular white matter of patients with benign intracranial hypertension, whereas no significant changes are seen in gray matter (Figure 9). Thus, it seems that the increased apparent diffusion coefficient of water in gray matter observed by Soelberg Sørensen et al.²⁸ can most likely be ascribed to pulsatile brain movements, which may be more pronounced in these patients than in healthy volunteers. Quantitative measurements of T_1 and T_2 of gray and white matter, respectively, show no differences between patients with benign intracranial hypertension and healthy volunteers.²⁸ In accordance with this, T_1 - and T_2 -weighted images do not show any abnormalities, indicating that quantitative diffusion imaging is much more sensitive to alterations in intra- and extracellular water balance and dynamics.

3.2.5 Brain Edema

Sevick et al.²⁹ have studied the influence of *cytotoxic edema* secondary to hyponatremia on the apparent diffusion

Figure 8 (a) T_2 -weighted and (b) calculated apparent water diffusion coefficient images obtained from a patient with normal-pressure hydrocephalus. There is an increased diffusion in the periventricular white matter as compared with normal subjects. (Reproduced by permission from Gideon et al.⁶)

Figure 9 (a) T_2 -weighted and (b) calculated apparent water diffusion coefficient images obtained in a patient with benign intracranial hypertension. Note the marked increase in D^* in the periventricular white matter in the diffusion images, whereas the T_2 -weighted image appears normal. (Reproduced by permission from Gideon et al.⁶)

coefficient of water in rat brain. The results suggest that cytotoxic edema reduces the apparent diffusion coefficient of water in the brain by about 10%, and there seems to be an inverse relationship between the calculated D^* value and the total water content of the brain tissue. It cannot, however, be totally excluded that the results may at least partly have been influenced by a concomitant reduction in pulsatile movements of the edematous brain, since no cardiac triggering or compensation for first order movements was performed. Anyway, the relatively small decrease in the apparent diffusion coefficient observed in cytotoxic brain edema does not explain the alterations seen in acute brain ischemia described in a previous section.

A number of studies indicate that the apparent diffusion coefficient of water is higher in tumor-induced *vasogenic brain edema* than in normal gray and white matter¹³ (cf Figure 6).

Taken together, the preliminary evidence suggests that quantitative diffusion studies may make it possible to differentiate between cytotoxic (D^* reduced) and vasogenic brain edema (D^* increased).

3.2.6 Pediatric Disorders

The experience with diffusion studies of infants is very limited at present. Rutherford et al.³⁰ have recently published a study in which they examined 31 neonates and infants with various disorders of the brain. They did not calculate the apparent diffusion coefficient. *Cysts* and *fluid collections* are recognized by their hypointense signals, indicating an increase in the D^* value of water. Low signal intensities are seen in *chronic infarcts*, consistent with a relatively free isotropic diffusion, whereas the signals are low in *intracerebral*

hematomas, suggesting restricted isotropic diffusion. Patients with *leukodystrophy* associated with congenital muscle dystrophy reveal an anisotropic diffusion pattern. In three cases, abnormalities can be seen in the diffusion-weighted images despite conventional imaging being normal. Finally, abnormalities in the corticospinal tract are frequently seen in children with a history of *birth asphyxia*.

Even though the retrospective character of the study does not allow any definite conclusions to be drawn, the results are very promising, indicating that diffusion studies may contribute to the diagnosis of a number of pediatric brain disorders. Before reaching that point, however, a large number of systematic studies with quantitative measurements of the apparent diffusion coefficient of water are warranted in order to interpret the signal changes which are seen in the diffusion-weighted images.

4 OTHER ORGANS

Only a very limited number of diffusion studies of organs other than the brain are available at present. The reason is that diffusion studies may be hampered by considerable gross movements of the organ, caused by respiration and arterial pulsation.

Evidence of anisotropic water diffusion has been obtained in *human skeletal muscle*. The apparent diffusion coefficients of water range from 1.1×10^{-9} to $1.5 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$ perpendicular to and are about $2 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$ parallel to the muscle fibers, giving an anisotropic ratio of about 0.7.^{31,32}

The ability to map changes in tissue temperature noninvasively in vivo has been investigated in human skeletal muscle during hyperthermia.³³⁻³⁵ Noninvasive mapping of tissue temperatures in vivo may offer great clinical potential in the control of hyperthermia therapy. The question is whether diffusion measurements as described above are sufficiently accurate and reproducible. A study by Morvan et al.³⁵ suggests that it is possible to measure temperature differences of approximately 2°C. This approach should be compared with an alternative method where changes in resonance frequencies induced by alterations in tissue temperature are measured.³⁶ The latter method may turn out to be more sensitive and reproducible.

Preliminary studies indicate that it may be possible to obtain meaningful diffusion-weighted images of *human kidneys in vivo* by means of an ultrafast diffusion-sensitized echo planar imaging sequence.³⁷ It is much too early to speculate on the clinical significance, however, because water transport in the kidney is very complex. Furthermore, substantial sources of error due to motion have to be taken into account. Ultrafast techniques combined with breath holding may be a part of the solution.

5 DIFFUSION-WEIGHTED SPECTROSCOPY

Recent developments in localized spectroscopic techniques have made it possible to take advantage of chemical shift information to extend diffusion measurements to include molecules other than water. By means of ³¹P spectroscopy it is possible to study the diffusion of various phosphorus compounds, including phosphocreatine, in skeletal muscle.³⁸ Diffusion characteristics of *N*-acetylaspartate, total creatine, and choline-containing compounds have been measured in anesthetized rat brain,³⁹ and recently also in human brain,⁴⁰ using a diffusion-sensitized localized proton spectroscopic sequence with water suppression. The calculated apparent diffusion coefficients (mean ± 1 SD) of *N*-acetylaspartate, choline-containing compounds, and total creatine in normal human brain are $(0.18 \pm 0.02) \times 10^{-9}$, $(0.13 \pm 0.03) \times 10^{-9}$, and $(0.15 \pm 0.03) \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$, respectively.⁴⁰

Applications of diffusion-weighted spectroscopic techniques are very interesting because compounds which do not penetrate the cell membranes can be used to study the intracellular medium, including viscosity, cell dimensions, etc. At present, the drawback is relatively poor spatial resolution, which means that the calculated *D** values represent a weighted average of diffusion coefficients in a mixture of tissue types consisting of many different cell types.

6 CLINICAL UTILITY OF MRI DIFFUSION STUDIES: A GENERAL VIEW

Although clinical experience with diffusion imaging is rather limited, it is possible to outline some general trends with respect to clinical utility. So far the method has almost exclusively been applied to the brain, because problems due to movement can be dealt with, and secondly, the relatively high *T*₂ values make it possible to achieve a reasonable signal-to-noise ratio at the long echo times which are necessary in order to obtain sufficient diffusion sensitivity.

One of the most striking areas for the use of diffusion-weighted imaging is early visualization of brain ischemia. This will most likely have a great impact on treatment strategies, where success depends critically on a very early start to intervention. Further research is needed in order to evaluate the prognostic information of alterations in diffusion characteristics, with particular emphasis on questions related to the penumbra zones.^{41,42} Studies on anisotropy during the course of infarction may give new information about pathophysiological mechanisms operating during severe brain ischemia.

Secondly, diffusion studies may contribute to tissue characterization in the brain and thus improve the specificity of MRI investigations, taking advantage of the information related to anisotropy. Such studies may contribute to the separation of solid tumors and edema, identification of fluid compartments, and maybe also to differentiation between cytotoxic and vasoactive edema. Quantitative diffusion imaging is very sensitive to subtle changes in water balance and viscosity, as observed in patients with benign intracranial hypertension, where imaging by all other imaging modalities, including radio isotope techniques, is normal.

Thirdly, it is most likely that diffusion studies will contribute significantly to the characterization of brain white matter disorders. Alterations in diffusion anisotropy may give information of lesions in specific nerve tracts. Quantitative measurements of the apparent diffusion coefficients may contribute, for example, to the differentiation between acute and chronic multiple sclerosis lesions.

Diffusion-weighted spectroscopy may offer unique information about specific molecules. The study of chemical compounds which do not penetrate cell membranes and other structures makes it possible to obtain information about cell dimensions, intracellular fluid viscosity, etc.

It is important to avoid errors due to motion in diffusion studies. Cardiac gating and compensating for first-order movements are mandatory unless single acquisition techniques such as echo planar imaging are used. Quantitative measurements of apparent diffusion coefficients in pathologies are needed in order to obtain the knowledge necessary for interpreting the diffusion-weighted images where the signal intensity is also influenced by proton density, and *T*₁ and *T*₂ relaxation.

Thus, diffusion-weighted imaging is a very challenging field which offers great potential for biomedical research and diagnosis. Systematic clinical studies are now required in order to define the clinical indications for diffusion-weighted imaging by magnetic resonance.

Methods and Applications of Diffusion MRI

Denis Le Bihan

Service Hospitalier Frédéric Joliot, CEA, Orsay, France

1 INTRODUCTION

Diffusion is the process by which matter is transported from one part of a system to another as a result of random molecular motion, also called Brownian motion. This motion, of thermal origin, results in the macroscopic flux of different molecular species, which can be observed in nonuniform systems and is characterized by a diffusion coefficient. Classically, diffusion coefficients may be determined by measuring the concentration of molecular species at different times using either physical or chemical methods based on the classical first Fick Law.¹ Such approaches rely on the introduction of a tracer in the medium, as similar as possible to the studied molecular species, and then monitoring the concentration of the tracer in the medium by chemical or radiotracer techniques.² Microscopic displacements on the scale of millimeters can be seen with such tracers over diffusion times of minutes. Such tracer methods have been successfully applied to biological systems, such as the brain³ but are, of course, extremely invasive. An alternative in studying diffusion is to monitor the random walks of molecules. On a statistical scale, the diffusion reflects the mean-square distance traveled by molecules in a given interval of time ($\text{m}^2 \text{s}^{-1}$). Diffusion NMR, which relies on these principles, is the only method today available to provide noninvasively such information on molecular displacements which occur over diffusion distances that extend largely beyond elementary molecular jumps, justifying the considerable success of diffusion NMR in physics and chemistry, and more recently in biology.⁴ Taking typical values for water diffusion ($\sim 1 \times 10^{-3} \text{ mm}^2 \text{s}^{-1}$) and diffusion time ($\sim 20 \text{ ms}$) achievable on conventional MRI equipment free water molecules diffuse over distances on the order of $6 \mu\text{m}$, which is about the size of many tissue structures. NMR has, in principle, a displacement sensitivity of around 100 nm .⁵ Because of its noninvasive nature, it is especially suited to probing the molecular dynamics and structural information of biological systems, as well as transport processes. The recent combination of such principles with MRI⁶⁻⁸ represents a spectacular and somewhat unpredicted development in the field of medical sciences. Measuring molecular displacements in biological tissues in vivo may have enormous value, from the determination of the molecular organization in tissues to the emergency management of stroke patients or the monitoring of laser surgery. In this chapter, the basic principles of diffusion measurements with NMR will be presented, as well as the various methods that have been proposed to produce images of diffusion. Some technical considerations will be discussed, followed by a description of the effects on diffusion measurements of microdynamic and microstructure in biological tissues. Emphasis

will be given to the difficulties encountered when implementing diffusion imaging and the potential of diffusion measurements for clinical applications.

2 DIFFUSION MRI

Although the effects of diffusion on the NMR signal have been described very early,^{9,10} most diffusion NMR studies started after the seminal work of Stejskal and Tanner, who introduced the bipolar pulse field gradient method (Figure 1).¹¹ This approach not only provides much better control over what is actually measured but also simplifies the understanding of the encoding of the diffusion process in the NMR signal. The purpose of these gradient pulses, the duration and the separation of which are classically represented, respectively, as δ and Δ , is to label spins carried by diffusing molecules magnetically. To some extent, these labeled spins are like the endogenous tracers that can be monitored with classical diffusion measurement tracer methods. However, the behavior of these labeled spins in an NMR experiment leads to more peculiar and specific results that are unique to diffusion NMR, and diffusion data obtained with NMR may not always be directly comparable with those obtained by other means.

The first gradient pulse induces a phase shift φ_1 of the spin transverse magnetization, which depends on the spin position z_1 :

$$\varphi = \gamma G \delta z_1 \quad (1)$$

where γ is the gyromagnetic ratio and G is the gradient strength (here, along the z axis). After the 180° rf pulse, φ_1 is inverted to $-\varphi_1$. The second pulse will produce a phase shift φ_2 :

$$\varphi_2 = \gamma G \delta z_2 \quad (2)$$

where z_2 is the spin position during the second pulse. The net transverse magnetization M_{xy} is:

$$M_{xy}/M_0 = \exp[i(\varphi_2 - \varphi_1)] = \exp[i\gamma G \delta (z_2 - z_1)] \quad (3)$$

where all relaxation effects have been incorporated into M_0 .

Figure 1 Stejskal and Tanner diffusion spin-echo sequence. Gradient pulses, G , are separated by a time interval Δ . Their duration is δ

Obviously for ‘static’ spins, $z_1 = z_2$ and the bipolar gradient pair has no effect. For ‘moving’ spins, however, there is a net dephasing that will depend on the spin history during the time interval Δ between the pulses. Indeed, we must now consider a population of spins, which may have different motion histories. This leads to an attenuation of the M_{xy} and the resulting signal. Assuming $\delta \ll \Delta$ (negligible displacement during δ), these equations give a time-dependent part that represents the attenuation owing to diffusion, A :

$$A = \int dz_1 P(z_1) \int \exp[i\gamma\delta G(z_2 - z_1)] P(z_2, z_1, \Delta) dz_2 \quad (4)$$

where $P(z_1)$ is the probability for a labeled spin to be at initial position z_1 and $P(z_2, z_1, \Delta)$ is the diffusion propagator, i.e., $P(z_2, z_1, \Delta) dz_2$ is the conditional probability to find a labeled spin initially at position z_1 in position z_2 after a time interval Δ . For a true, isotropic diffusion process:

$$\partial P(z_2, z_1, t) / \partial t = D \nabla^2 P(z_2, z_1, t) \quad (5)$$

and P is Gaussian, at $t = \Delta$:

$$P(z_2, z_1, \Delta) = (4\pi D \Delta)^{-1/2} \exp[-(z_2 - z_1)^2 / 4D\Delta] \quad (6)$$

where D is the diffusion coefficient.

Combining Equations (1) and (2) gives:

$$A = \exp[-(\gamma\delta G)^2 \Delta D] \equiv \exp[-(\gamma\delta G)^2 \langle z^2 \rangle / 2] \quad (7)$$

where the root mean square diffusion displacement $\langle z^2 \rangle$ that occurred during the diffusion time Δ is easily interchangeable with D according to Einstein’s equation, $\langle z^2 \rangle = 2DT_d$. Diffusion coefficients or root mean square diffusion distances are classically obtained by varying either G or δ and by measuring the slope of the semilogarithmic plot of the signal intensity versus $(\delta G)^2$. However, it is the diffusion path that the NMR experiment is actually sensitive to, not the diffusion coefficient. Therefore, in this simple bipolar gradient experiment, clear information on spin displacements can directly be obtained from the signal attenuation A , assuming P is Gaussian. This model is valid only for diffusion in an infinite and homogeneous medium. If diffusion is restricted or anisotropic (see below), the signal attenuation must be calculated using a more general formalism based on diffusion tensors.¹²

2.1 Diffusion and the NMR Signal: Different Approaches

Almost any NMR sequence can be designed to measure diffusion.

2.1.1 Constant Field Gradient Spin Echo Method

In the presence of a simple constant linear gradient G_0 , the echo attenuation is:^{9,10}

$$A(nTE) = \exp(-\gamma^2 G_0^2 D TE^3 / 12n) \quad (8)$$

where TE is the echo time and n the echo number in a multiple echo experiment. This simple approach is difficult to combine with NMR imaging because the presence of a constant gradient during the rf pulses of the imaging sequence severely impairs

the selected slice profile. In addition, the relaxation time T_2 of the medium must not be too short to allow enough diffusion attenuation to occur during TE .

2.1.2 Bipolar Gradient Pulse Spin Echo Technique

The bipolar gradient pulse spin echo technique is, by far, the sequence most widely used for NMR diffusion measurements. In practice, as δ is usually not negligible compared with Δ , movement during the application of the gradient pulses can no longer be neglected. Taking into account spin diffusion during δ , Equation (7) becomes:¹¹

$$A = \exp[-\gamma^2 G^2 D \delta^2 (\Delta - \delta/3)] \quad (9)$$

The diffusion time can be formally defined as $(\Delta - \delta/3)$, but its physical significance is clear only when δ is sufficiently short compared with Δ . Tissues with short T_2 times require short TE values, which may not allow sufficiently long diffusion times to produce enough diffusion effects.

2.1.3 Stimulated Echo Technique

A stimulated echo is generated from a sequence consisting of three rf pulses separated by time intervals τ_1 and τ_2 . Gradient pulses must be inserted within the first and the third periods of the stimulated echo sequence (Figure 2).

The diffusion time now includes τ_2 and can be much longer than with the spin echo sequence without T_2 -related signal decay because only longitudinal relaxation occurs during this time interval. The Stejskal–Tanner relation [Equation (9)] still applies, provided that the period τ_2 is included in Δ .¹³ The longer diffusion time is useful for studying very slow diffusion rates or for compensating for the unavailability of large gradients.⁷ Unfortunately, the signal is reduced by 50% compared with the spin echo signal.

2.1.4 Gradient Echo Technique

The effect of diffusion on the amplitude of a gradient echo formed by a bipolar gradient pulse pair of reversed polarity does not differ from that of a spin echo sequence.¹⁴ However, if the gradient echo is part of a steady-state free precession (SSFP) sequence, where some degree of phase coherence is

Figure 2 Diffusion-stimulated echo sequence. The stimulated echo results from the spin excitation by three rf pulses separated by time intervals τ_1 and τ_2 . During τ_2 , relaxation is driven by T_1 and not T_2 . Diffusion effects can be enhanced by placing gradient pulses within the τ_1 periods, where transverse magnetization is sensitive to field inhomogeneities

propagated throughout successive cycles, multiple echo paths with different diffusion times and different diffusion weighting must be considered.¹⁵ In MRI, the contrast-enhanced (CE-Fast) scheme has been proposed.^{16–18} Unfortunately, this sequence remains very sensitive to motion artifacts.¹⁹ Moreover, the effects of diffusion and relaxation are mingled so that diffusion measurements are always contaminated to some degree by relaxation effects.²⁰

2.1.5 Diffusion Measurements with B_1 Field Gradients

Diffusion measurements can also be achieved by means of the rf (B_1) field produced by a NMR rf coil oriented perpendicularly to the main transmit/receive NMR coil.^{21–24} With rf gradients, extremely short switching times can be achieved since there are no eddy currents. Furthermore, substantial gradient strength may be produced from the rf transmitter, allowing measurements of very low diffusion coefficients.

2.2 Combining Diffusion NMR with MRI

2.2.1 Principles

Diffusion-weighted (DW) images are obtained by inserting gradient pulses into any NMR imaging sequence. For quantification, it is necessary to determine the degree of diffusion weighting of the sequence. When inserting gradient pulses for diffusion, however, the combination of the imaging and the diffusion gradient pulses produces cross-terms. These cross-terms, which depend on the sequence design, may also lead to significant diffusion-related attenuation effects,^{14,25} which must be taken into account; consequently the Stejskal–Tanner relation [Equation (9)] is incorrect in most cases. A more general formalism must then be developed to solve the Bloch–Torrey equation.²⁶ Solutions may become analytically complex,²⁷ and it has been suggested that all gradient effects should be combined in a term generally known as the ‘ b factor’.^{14,28}

$$b = \gamma^2 \int_0^{TE} \left[\int_0^t \mathbf{G}(t') dt' \right]^2 dt \quad (10)$$

The signal attenuation for, unrestricted, isotropic diffusion is then reduced to a simple, convenient expression:

$$A = \exp(-bD) \quad (11)$$

This b factor characterizes the diffusion sensitivity of the sequence, as TE characterizes the degree of T_2 weighting of a spin echo sequence. Without additional gradients, typical spin echo imaging sequences have intrinsically very low b values, typically less than 1 s mm^{-2} ; consequently diffusion effects are negligible (for pure water at room temperature the attenuation is less than 1%).^{14,29}

As the raw signal depends not only on diffusion but also on other MR parameters, such as T_1 or T_2 , a quantitative determination of the diffusion coefficient requires at least two images acquired with different diffusion sensitivities (i.e., b factor values), but better accuracy is obtained when more than two images are used (see below). With the b factor values associated with each image, it is possible to compute diffusion images, i.e., images where the diffusion coefficient is determined for each pixel. The computation of such diffusion

Figure 3 The relationship of the logarithm of the signal intensity in brain white matter with the gradient factor b is linear; the slope is equal to the diffusion coefficient $D=0.60 (\pm 0.01) 10^{-3} \text{ mm}^2 \text{ s}^{-1}$

images is obtained by fitting the signal intensity of each pixel obtained for different b factor values with Equation (11)^{4,6,7,14,28} using a regression analysis (Figure 3).

On diffusion images, diffusion values are displayed using a gray scale where brightness corresponds to high, fast diffusion and darkness to low, slow diffusion (Figure 4). To save on acquisition and processing time, some investigators have proposed to limit the diffusion studies to the analysis of the raw images obtained with some degree of diffusion sensitivity or weighting. For this reason, these images are called DW images. Contrast in these images is opposite to that found in true diffusion images: regions with high diffusion have more pronounced MRI signal attenuation and appear dark, while regions with low diffusion appear bright. The DW image may be convenient to use, but its content is affected by many parameters other than diffusion, as it is also usually strongly T_1 and T_2 weighted. As these parameters may not have the same behavior as diffusion, variations in image intensity may be difficult to interpret. For instance, acute stroke lesions have decreased diffusion (see below) and appear bright on DW images, while subacute infarcted areas, which are associated with increased diffusion, may also appear bright on DW images because T_2 has increased (T_2 ‘shine-through’ effect). DW images may be convenient to use in clinical practice, but, whenever possible, absolute diffusion images should be preferred.

2.2.2 Diffusion MRI Sequences

Using the spin echo sequence, it is possible to vary the strength or the duration of the diffusion-sensitizing gradients or their direction in order to enhance anisotropic diffusion effects¹⁴ (see below). The spin echo two-dimensional Fourier (2DFT) method is certainly the simplest to implement.^{6,8,28,29} Other sequences⁴ that have been investigated are stimulated echo sequences,⁷ line-integral projection reconstruction,^{30–32} variants of the SSFP technique; and ‘turbo’ sequences such as HASTE,³³ TurboFlash³⁴ and fast spin echo.³⁵ These schemes have been suggested to overcome, at least partially, some of the problems encountered with the spin echo 2DFT method.

Figure 4 Diffusion image (left) calculated from a set of 16 diffusion-weighted coronal echo-planar images of the brain of a normal volunteer. These are 64×64 pixel images with a field of view of 16 cm and, therefore, an in-plane resolution of $2.5 \text{ mm} \times 2.5 \text{ mm}$. The section thickness was 10 mm. The diffusion gradients varied from 0 to 38 mT m^{-1} in the z direction; the duration of each lobe was 20 ms and their separation was 6 ms ($b=0$ to 872 s mm^{-2}). The acquisition time for each image was about 50 ms. Note that diffusion is the highest in ventricular cavities containing cerebrospinal fluid (free water). Because of diffusion anisotropy, diffusion along the x axis in corpus callosum is very low, while vertical frontal white matter tracts has the higher diffusion (see Table 1)

However, echo planar imaging (EPI) remains generally the imaging method of choice.^{36–39} With EPI, the entire set of echoes needed to form an image is collected within a single acquisition period (single shot) of 25–100 ms. This is obtained by switching the echo signal formation in a train of gradient echoes by means of a large gradient in which polarity is very rapidly inverted as many times as is required to achieve the desired image resolution.⁴⁰ EPI may easily be sensitized to diffusion (Figure 5).^{36–39}

Sensitization consists of providing a pair of large compensated gradients for a period of time before rapid gradient switching and data acquisition. The refocusing may be achieved either by simply reversing the polarity of the gradient halfway through the period over which it is applied or by inserting a 180° rf refocusing pulse at the midpoint without reversing the gradient polarity.

Figure 5 Diffusion echo planar imaging sequence. The spin echo is split into a series of gradient echoes by quickly switching the readout gradient. Sensitization to diffusion of an echo planar imaging sequence can be easily achieved by additional gradient pulses (dashed boxes)

With EPI, motion artifacts are virtually eliminated. The accuracy of assessments of diffusion achieved with EPI is generally extremely good, as many images differently sensitized to diffusion can be generated because of the very short acquisition time (typically less than 100 ms). The EPI technique is the method of choice for in vivo diffusion imaging, although it is very vulnerable to susceptibility artifacts, which are responsible for image distortion or signal dropout and to chemical shift artifacts, which require efficient fat suppression. Despite this, diffusion-EPI has become widely available on many clinical scanners and has been successfully used for measuring diffusion of water in the human brain in volunteers (Figure 4)^{37,41} and patients (see below).

Recently, alternative fast acquisition schemes, such as BURST^{42,43} and spiral MRI,⁴⁴ have been proposed to overcome some EPI artifacts, such as ghosting or susceptibility artifacts.

2.2.3 Sequence Optimization

Although the b factor can be exactly determined for any pulse sequence,^{27,45} the diffusion time is impossible to define accurately for a MR sequence where gradient pulses of finite duration are scattered all over the pulse sequence. A mixture of diffusion-related events with differently weighted contributions are obtained depending on their sequence in time with respect to the many pulse gradients. That is why it has been suggested that the parameter derived from the NMR signal attenuation using Equation (7) should be called an ‘apparent diffusion coefficient’ (ADC).²⁸ MR sequences should be designed to minimize these problems, i.e., by placing gradient pulses to get as close as possible to the simple Stejskal–Tanner bipolar pulse sequence. However, the use of the ADC term remains justified,

as biological tissues usually differ significantly from the ideal 'free, unlimited, isotropic' medium.

Another issue is to optimize the values and the number of b factors to be used. A simple calculation⁴ shows that the best accuracy for the diffusion coefficient is obtained from a set of two acquisitions if the two b factors, b_1 and b_2 differ by about $1/D$.⁴⁶ In the brain, this translates to $(b_2 - b_1) \sim 1000$ to 1500 s mm^{-2} . If more than two acquisitions are to be used, error propagation theory⁴⁷ shows that it is better to accumulate n_1 and n_2 measurements at each of the small and large b factors, b_1 and b_2 , than to use a range of b factors. The accuracy dD/D can be obtained from the raw image signal-to-noise ratio (SNR):

$$dD/D = [1/n_1 + \exp[2D(b_1 - b_2)]/n_2]^{1/2} / [(SNR)D(b_1 - b_2)] \quad (12)$$

Acquisition performed with linear sets of b value ranges remains, however, extremely useful to validate the sequence/hardware quality and to assess the nature of the diffusion process or the presence of multiple diffusion compartments as it allows the exponential diffusion attenuation to be visualized according to Equation (11).

2.3 Experimental Considerations in Diffusion MRI

2.3.1 Gradient Hardware

Since the minimum length of molecular diffusion paths detectable with gradient-pulsed NMR is primarily determined by the intensity of the gradient pulses, hardware must be capable of providing stable gradients of the utmost intensity.⁴⁸ This requirement may be extremely challenging when considering whole-body instruments designed for clinical studies. The lack of gradient power is usually compensated by using somewhat long gradient pulse widths; as a result, the classical condition $\delta \ll \Delta$ is not satisfied. The case of such finite pulse widths is significantly more difficult to treat and to interpret compared with the situation with δ -sharp pulses. If the duration of the pulses is ignored, significant underestimation of the diffusion distances may result.⁴⁹ For instance, to achieve at least a 20% signal attenuation and limit signal loss from transverse relaxation, the minimum diffusion coefficient $D_{\min}$ measurable is $37 \times 10^{-3} \text{ mm}^2 \text{ s}^{-1}$ using $\delta = \Delta/10$, $\Delta = T_2 = 100 \text{ ms}$, and $G_{\max} = 10 \text{ mT m}^{-1}$, which is more than 16 times the diffusion coefficient of free water!¹⁴ Maximum sensitivity is achieved when $\delta = \Delta$ (equivalent to a constant gradient) and $\Delta = T_2/2$. Then $D_{\min}$ is $0.4 \times 10^{-3} \text{ mm}^2 \text{ s}^{-1}$. There are partial solutions to this problem, such as using stimulated echoes to increase the effective diffusion time without penalizing the signal by T_2 relaxation effects,¹³ or, better, by building high-performance gradient coils (e.g., up to 50, 100 or even 200 mT m^{-1}). Safety should not be too much a concern, considering that slew rates will remain low, as there is no need to switch such gradient coils very rapidly (which also limits eddy currents). Hence, diffusion effects during the application of the gradient pulses can no longer be neglected, although their contribution to the overall signal attenuation does not scale the same way with time as

for diffusion occurring between pulses. The diffusion time then becomes more difficult to define, although $(\Delta - \delta/3)$ is often taken instead of Δ as the efficient diffusion time.¹¹

Another concern is that any mismatch between the diffusion-sensitizing gradient pulses may cause artifactual signal losses through an improper spin rephasing. Two major sources of problem are commonly seen. One is gradient instability, which may arise when gradient amplifiers are driven hard for fast switching of large gradient intensities. Variations from shot to shot of the bipolar gradient balance result in widely distributed ghost artifacts. While such artifacts do not occur when a single-shot technique such as EPI is used, it is still essential to have high-quality gradient amplifiers with some reserve capacity for accurate diffusion imaging. The second problem results from eddy currents generated mainly in the cryostat when switching large gradient pulses rapidly. Eddy currents may also be a major cause of image distortion and misregistration between images obtained with different b values, leading to ADC miscalculation. The best solution to this problem is undoubtedly to remove eddy currents at the source by using actively shielded gradient coils, which have no fringe fields and, therefore, do not generate eddy currents. The use of a gradient coil of small dimensions, which remains at a fair distance from the magnet core and with which it is easier to generate large gradient amplitudes, is certainly an attracting alternative.²¹ If residual eddy current effects persist, other approaches can be combined.^{50–52}

In summary, there is clearly a need for very-high-performance gradient coils. With the hardware that is now becoming available,^{53,54} shorter diffusion times or larger b values can be reached while maintaining high SNR, giving access to slow diffusion components (e.g., intracellular water, metabolites).

2.3.2 Motion Artifacts

As the sequences used are deliberately sensitized to motion by the addition of large gradients, a major problem occurring with in vivo imaging of diffusion arises from motion of the object. Artifacts result from discontinuities that occur between successive cycles of an imaging sequence. Results of such temporal incoherence are commonly visible as 'ghosts' along the phase-encoding direction. These ghosts are particularly intense in the presence of the diffusion gradients and render the diffusion measurements meaningless. Cardiac gating has been used to mitigate this problem, but even this motion is not strictly cyclic. It is difficult to compensate diffusion imaging sequences for motion, since the use of successive bipolar gradient pulses considerably reduces the value of the b factor.^{4,14} Chenevert et al. have suggested eliminating any phase encoding from the acquisition by sacrificing one dimension of the image, which is then reduced to a single line.^{55,56} Ultimately, however, the best way to avoid motion artifacts is to use a single-shot technique, such as EPI, and to secure patients comfortably within the magnet using cushions or inflating devices. In spite of this, motion artifacts may persist, especially when multiple shots are used, as with diffusion spectroscopy (see below) or segmented EPI. Motion effects can be estimated by monitoring the phase of the signal and corrected.^{57,58} Navigator echoes have been used with some success by several investigators.^{59–62}

2.3.3 Background Inhomogeneities

In addition to the magnetic field gradient pulses, residual field inhomogeneities arising from the imperfect shimming of the magnet and from inhomogeneities in the sample must be considered. These inhomogeneities result from susceptibility variations, especially at high field, and may not be negligible.⁶³ By adding a constant, linear gradient G_0 , it is clear that two contributions of the residual gradients coexist.¹¹ One is a unique contribution (term in G_0^2); the other results from a cross-term between the residual and the applied gradients (GG_0 term).¹⁴ While the first contribution can easily be eliminated from a series study where only G is varied, the second term is more difficult to handle. There are however, diffusion pulse sequences that have been designed to reduce significantly or to eliminate effects of background gradients.^{64–70} Most of them are based on multiple rf pulses. For instance, cross-terms can be completely eliminated by alternating the gradient pulses between the successive 180° rf pulses of a quadrupole spin echo sequence.⁷¹

If cross-terms with the background gradients are not eliminated, the logarithm of A is no longer linear with the b factor and the ADC overestimates the true diffusion coefficient.²⁵ The ADC will, furthermore, appear as a function of the diffusion time. The examination of the linearity of the relationship between $\log A$ and b is therefore, the first step in interpreting any NMR diffusion study in biological tissues, although there are several possible causes that would explain a deviation from linearity. Notably, similar nonlinear behavior will be seen if the b factor is miscalculated, i.e., cross-terms coming from all applied (diffusion and imaging) gradient pulses are not appropriately considered in the calculation.²⁷ The b factor must be carefully calculated before the presence of background gradients can be assessed.

However, finding a linear plot for $\log A$ versus b does not exclude background gradients. First, the effect may be small. Second, the interpretation of the data may become very complicated when gradients are nonuniform or nonlinear and slowly varying in space, as in the case of capillaries filled with materials with a high susceptibility constant (e.g. contrast agent). Simulations and experiments have shown, in this case, that the ADC is decreased and that the parameter to consider is the variance of the internal gradients.^{72,73}

The ultimate test to evaluate background gradients, however, is to vary TE while δ and Δ are kept constant. The measured ADC should normally be independent of TE . Otherwise, the contribution of background gradients must be suspected. Furthermore, as self-induced gradients may depend on the orientation of the sample with respect to the direction of B_0 , they may cause isotropic diffusion to appear anisotropic.⁶⁵ In this case also, the measured diffusion coefficient depends on the diffusion time.

Once it is established that background gradients are present, it may be desirable to estimate them from the attenuation behavior in order to obtain information on the structure of the medium. For instance, in the ideal case where the internal gradients result from inhomogeneities caused by the presence of closely packed particles, a rough estimation of the mean size R , of these particles can be obtained from:⁷⁴

$$R \approx 6\chi_0 B_0 / G_0 \quad (13)$$

where χ_0 is the magnetic susceptibility constant. Furthermore, these susceptibility effects may be of biological interest,⁷⁵ as variations in the oxygenation level in brain capillaries and small vessels following brain activity have been shown to induce susceptibility effects measurable by T_2^* .^{76,77} A significant drop of the measured ADC has also been observed during status epilepticus,⁷⁸ cortical electroshocks⁷⁹ and spreading depression.^{80–82} In all cases, large increases in oxygenated blood flow could result in important reductions in local internal gradients and apparent variations to diffusion, although cytotoxic edema and cell swelling associated with energy failure has been mainly evoked as the reason for this diffusion drop.

2.4 Other Approaches to Diffusion

2.4.1 Diffusion Tensor Imaging

Diffusion is a three-dimensional process. However, the molecular mobility may not be the same in all directions. This anisotropy may be a result of the physical arrangement of the medium (liquid crystal) or the presence of obstacles that limit diffusion in some directions. The result is that the ADC appears different when pulse gradients are imposed in different directions; this has been observed in muscle⁸³ and, more recently, in brain white matter.^{37,56,84}

The proper way to study anisotropic diffusion is to consider the diffusion tensor.^{1,11} Diffusion is no longer characterized by a single scalar coefficient but by a tensor $\underline{D}$, which fully describes molecular mobility along each axis and the correlation between these axes:

$$\underline{D} = \begin{pmatrix} D_{xx} & D_{xy} & D_{xz} \\ D_{yx} & D_{yy} & D_{yz} \\ D_{zx} & D_{zy} & D_{zz} \end{pmatrix} \quad (14)$$

In the reference frame $[x', y', z']$ that coincides with the principal or main directions of diffusivity, the off-diagonal terms do not exist and the tensor is reduced only to its diagonal terms $D_{x'x'}$, $D_{y'y'}$, $D_{z'z'}$, which represent molecular mobility along axes x' , y' , and z' , respectively. The echo attenuation then becomes:

$$A = \exp(-b_{x'x'} D_{x'x'} - b_{y'y'} D_{y'y'} - b_{z'z'} D_{z'z'}) \quad (15)$$

where b_{ii} are the elements of the $\underline{b}$ matrix (which now replaces the b factor) expressed in the coordinates of this reference frame.

In practice, measurements are made in the reference frame $[x, y, z]$ of the gradients, which usually does not coincide with that of the tissue. Therefore, one must also consider the coupling of the nondiagonal elements b_{ij} of the $\underline{b}$ matrix with the nondiagonal terms D_{ij} ($i \neq j$), of the diffusion tensor (now expressed in the gradient frame), which reflect correlation between molecular displacements in perpendicular directions.⁸⁵

$$A = \exp\left(-\sum_{i=x,y,z} \sum_{j=x,y,z} b_{ij} D_{ij}\right) \quad (16)$$

Calculation of the value of $\underline{b}$ may quickly become very complicated when many gradient pulses are used,⁴⁵ however, the full

determination of the diffusion tensor is necessary to assess anisotropic diffusion properly and fully.

To determine the diffusion tensor, DW images are collected along several gradient directions. As the diffusion tensor must be symmetric, measurements along only six directions are mandatory (instead of nine), along with an image acquired without diffusion sensitivity ($b=0$). A typical set of gradient combinations that preserves uniform space sampling and similar b values along each direction is as follows (coefficients for gradient pulses along the x , y , z axes, normalized to a given amplitude, G):

$$\begin{aligned} &[(1/\sqrt{2}, 0, 1/\sqrt{2}); (-1/\sqrt{2}, 0, 1/\sqrt{2}); (0, 1/\sqrt{2}, 1/\sqrt{2}); \\ &(0, 1/\sqrt{2}, -1/\sqrt{2}); (1/\sqrt{2}, 1/\sqrt{2}, 0); (-1/\sqrt{2}, 1/\sqrt{2}, 0)] \end{aligned}$$

This minimal set of images may be repeated for averaging, as the SNR may be low^{12,85}. In the case of ‘axial symmetry’, only four directions are necessary (tetrahedral encoding),⁸⁶ as suggested for the spine.⁸⁷ The acquisition time and the number of images to process is then reduced, but efforts should be made to collect data along as many directions in space as possible to avoid sampling direction biases for applications such as the determination of fiber orientation and gain in SNR (see below).⁸⁸ A second step is to estimate the D_{ij} values from the set of diffusion/orientation-weighted images, generally by multiple linear regression, using Equation (23) below. The final step is to determine the main direction of diffusivities in each voxel and the diffusion values associated with these directions. This is equivalent to determine the reference frame $[x', y', z']$ where the off-diagonal terms of $\mathbf{D}$ are null. This ‘diagonalization’ of the diffusion tensor provides ‘eigen-vectors’ and ‘eigen-values’, λ , which correspond, respectively, to the main diffusion directions and associated diffusivities,^{12,85} (the eigen-diffusivities λ are not to be confused with the tortuosity factors; see below).

As it is difficult to display tensor data with images (multiple images would be necessary), the use of ‘diffusion ellipsoids’ has been proposed.^{12,85} Ellipsoids are a three-dimensional representation of the diffusion distance covered in space by molecules in a given diffusion time (T_d). These ellipsoids, which can be displayed for each voxel of the image, are easily calculated from the eigen-diffusivities λ_1 , λ_2 , and λ_3 (corresponding to $D_{x'x'}$, $D_{y'y'}$, and $D_{z'z'}$):

$$x'^2/(2\lambda_1 T_d) + y'^2/(2\lambda_2 T_d) + z'^2/(2\lambda_3 T_d) = 1 \quad (17)$$

where x' , y' , and z' refer to the frame of the main diffusion direction of the tensor. These eigen-diffusivities represent the unidimensional diffusion coefficients in the main directions of diffusivity of the medium. The main axis of the ellipsoid gives the main diffusion direction in the voxel (coinciding with the direction of the fibers), while the eccentricity of the ellipsoid provides information about the degree of anisotropy and its symmetry (isotropic diffusion would be seen as a sphere). The length of the ellipsoids in any direction in space is given by the diffusion distance covered in this direction. In other words, the ellipsoid can also be seen as the three-dimensional surface of constant mean squared displacement of the diffusing molecules.

Recent work has demonstrated the feasibility of diffusion tensor imaging (DTI) in animal models, as well as in the human brain.^{41,86,89,90}

2.4.2 The Diffusion Propagator and q -space Imaging

In the case where diffusion deviates from the Gaussian model, as with restricted diffusion (see below), it becomes extremely difficult to get any meaningful information on molecular displacements from the measured NMR signals. The distribution of the propagator is no longer Gaussian; consequently the value obtained for the diffusion coefficient using Equation (11) may not necessarily properly reflect tissue structure of properties. Diffusion coefficients may become, in these conditions, meaningless. The main difficulty is that the medium structure is generally not known in detail and modeling is required. In particular, one must be cautious in the use of Fick’s Law and derived relations. The probability distribution driven by the diffusion process (Equation (6)) may now significantly deviate from a Gaussian distribution; as a result the relationship between A and b is no longer exponential as would be expected from Equation (7). A successful analysis should, therefore, start from a reformulation of the probability distribution, taking into account the medium structure and particular boundary or limit conditions. Hence, more useful information may be obtained by directly inferring molecular displacements from the MR signal attenuation without going through a diffusion coefficient formulation. Molecular displacement profiles, or more exactly their probability density distribution, can be obtained using q -space imaging.^{91,92} This does not differ, in principle, from diffusion imaging. Assuming $P(z_1)$ is homogeneous throughout the medium, Equation (4) can be rewritten by substituting the relative diffusion displacement z for $(z_2 - z_1)$ and by calling q the quantity $(\gamma\delta G)$ as:

$$A(q, \Delta) = \int \exp[iqz] P(z, \Delta) dz \quad (18)$$

It now appears that $P(z, \Delta)$ is just the Fourier transform of the attenuation $A(q, \Delta)$. By inverting Equation (15), direct and unequivocal data on molecular displacements can be obtained. In practice, data are collected for a series of different gradient strengths and an inverse Fourier transform is applied to the corresponding set of signal attenuation values. The experiment can be repeated with different values of Δ in order to characterize the probability distribution for different diffusion times.⁹³ With q -space imaging, a more comprehensive picture of the system under study is obtained than when using a unique ADC.⁹² It then becomes straightforward to verify whether $P(z, \Delta)$ is a Gaussian distribution and to determine the value of the diffusion time when the value of $P(z, \Delta)$ may start to deviate from a Gaussian behavior, suggesting that molecules have reached another structural order in the medium, or to obtain the molecular displacement distribution in different conditions. Localized q -space imaging has been used, for instance, to obtain water-displacement profiles from normal and ischemic mouse brain, showing an increase of the fraction of molecules undergoing displacements of less than $10 \mu\text{m}$.⁹⁴ Such findings are very useful for examining the microstructural changes occurring during acute brain ischemia (see below).

2.4.3 Diffusion Spectroscopy

Water may not be the most suitable molecule for diffusion measurements in biological tissues because of its ubiquity and the permeability of most tissue interfaces, such as membranes, to water molecules. Consequently, diffusion measurements of larger molecules that are more specific to a tissue or compartment appear to be more promising for tissue characterization. However, such measurements are technically more challenging, because of the low concentration of such molecules and their relatively low diffusion coefficients. Further, this requirement for signal averaging, and, therefore, long acquisition times, makes *in vivo* diffusion spectroscopy particularly sensitive to motion.^{57,95}

Recent progress made in *in vivo* Fourier NMR spectroscopy allows the extension of diffusion measurements to molecules other than water. For a given species, the chemical shift can be used to determine independent diffusion coefficients of compounds in complex mixtures.⁹⁶ Diffusion of phosphocreatine, for instance can be studied by ³¹P spectroscopy.^{97,98} Phosphocreatine is a true intracellular space probe, in contrast to water, which diffuses across cell membranes; as a result it can be used to observe true restricted diffusion. Phosphocreatine may be used to provide unique information on the intracellular medium, such as viscosity or geometry. Similarly, diffusion of *N*-acetylaspartate (NAR) and *myo*-inositol may provide useful information on neuronal and glial cell populations, respectively. Monitoring of exchanges of metabolites or drugs through cell membranes could also benefit from diffusion filter techniques designed to separate intracellular from extracellular compounds.⁹⁹ Although diffusion coefficients of metabolites are low because of their size, for nuclear species with spin >1/2 or for coupled-spin systems, multiple quantum experiments are less demanding on gradient hardware because the effective gradient amplitudes are increased by the power of the coherence order (*n*). With *n*=2, a fourfold increase in the diffusion effect would occur. Such spectral editing techniques have been used for selective measurement of diffusion properties of *J*-coupled compounds such as lactate.^{100,101}

3 DIFFUSION IN BIOLOGICAL SYSTEMS: EFFECTS OF MICRODYNAMICS AND MICROSTRUCTURE

Significant technical progress has been achieved in biological systems to ensure that meaningful data can be acquired with minimal artifacts. However, even in the ideal case with perfect data, the interpretation of diffusion NMR experiments performed in biological tissues remains challenging. The diffusion coefficient of water in tissues has been found to be two to ten times less than that of pure water (Table 1).¹⁴ This can be largely understood by considering that water molecules are obliged to divert tortuously around obstructions presented by fibers, intracellular organelles, or macromolecules. Water molecules may be confined in bounded compartments or retained by attractive centers or surfaces. Biological systems, therefore, differ greatly from an 'infinitely large medium'. They are very heterogeneous and made of multiple subcompartments (microstructure). Depending on the permeability of the barriers that limit these compartments, exchanges and transport between them (microdynamics) may occur. A classic treatment of the NMR signal may not then reflect properly tissue structure or

Table 1 Diffusion Coefficients of Water in Human Brain

	Mean diffusivity (10 ⁻³ mm s ⁻¹)	Anisotropy (1 – volume ratio)
Cerebrospinal fluid	3.19 ± 0.10	0.02 ± 0.01
Gray matter (frontal cortex)	0.83 ± 0.05	0.08 ± 0.05
Caudate nucleus	0.67 ± 0.02	0.08 ± 0.03
White matter		
Pyramidal tract	0.71 ± 0.04	0.93 ± 0.04
Corpus callosum (splenium)	0.69 ± 0.05	0.86 ± 0.05
Internal capsule	0.64 ± 0.03	0.70 ± 0.08
Centrum semiovale	0.65 ± 0.02	0.27 ± 0.03

Measurements (mean ± SD) were obtained in normal volunteers using diffusion tensor MRI. (With permission from Pierpaoli et al.⁴¹)

properties. Water molecules will 'sense' all these obstacles only if the time over which diffusion is measured is made sufficiently long that significant interaction of the water molecules with cellular compartments may occur. The concept of 'diffusion time' is, therefore, central to any diffusion study in biological tissues. While it may appear that using long diffusion times may reveal more tissue interactions, it is perhaps even more interesting to make the diffusion time as short as possible, up to the point where the diffusion coefficient will reach its value in pure water. By doing so, and plotting measured diffusion coefficients versus diffusion times, the many mechanisms contributing to *in vivo* diffusion may be revealed and identified. This approach, which will benefit from the newly developed gradient hardware allowing very large gradient strength, may be compared in some ways to that used in NMR dispersion studies, where multiple elementary relaxation mechanisms can be identified and separated by studying dispersion curves.¹⁰² Diffusion coefficients may become, in these conditions, meaningless if the measurement time scale or the measurement direction are not provided.

The main difficulty is that the medium structure is generally unknown in detail. The issue is, therefore, to infer meaningful information on tissue from the measured NMR signals. Initially, this problem could be reversed to consider how known tissue features relevant to tissue microstructure and dynamics affect diffusion NMR signals. Diffusion NMR has been used to study fluid-filled porous media and derive information on microstructure (shape of the pore space) and fluid permeability (porosity).^{103–105} It is clear that many of the questions addressed in those studies are relevant to diffusion measurements in biological media.⁵ Differences in diffusion coefficient and available diffusion space can be used to distinguish compartments and exchanges between them.⁹⁹

3.1 Effect of Temperature

The first obvious effect on diffusion is that of temperature, as diffusion directly results from the molecular thermal motion. The diffusion sensitivity to temperature is high, about 2.4% for 1°C change (Figure 6),^{106,107} consequently temperature must be carefully controlled in diffusion MRI experiments. Based on the strong and unique relationship that exists between temperature and molecular diffusion, diffusion imaging has been proposed for the real-time and noninvasive monitoring of tem-

Figure 6 Comparison of temperature measurements using T_1 and diffusion MRI, and using probes (Luxtron) in a phantom. The accuracy was found to be 0.2°C with diffusion and 0.5°C with T_1

perature. Noninvasive and nondestructive temperature imaging in biological systems may be particularly useful to monitor hyperthermia treatments in real-time, whether using rf electrical fields¹⁰⁸ or focused ultrasound.^{109,110} It could also be used to study and control tissue interactions in surgical and medical laser procedures. However, in the context of this chapter, the diffusion-temperature relationship also provides some indication about diffusion mechanisms in tissues.

This relationship has been established semi-empirically in liquids¹ and verified experimentally.^{106,111}

$$D = D_0 \exp(-E_a/kT) \quad (19)$$

where k is the Boltzmann constant, T is the temperature, D_0 is the diffusion that would be obtained at an infinite temperature, and E_a is introduced as the translational diffusion activation energy, which is approximately equal to the energy required to break hydrogen bonds, both in pure water and in vivo ($E_a=0.2$ eV).^{107,111}

This important result can be understood by considering that the mechanism at the molecular scale for water to move, and thus diffuse, involves continuous breaking and reforming of hydrogen bonds. The fact that E_a is identical for water molecules diffusing in vitro and in vivo is not really surprising as the laws of physics at this level should not be different.

3.2 Restricted Diffusion

Diffusion is restricted when boundaries in the medium prevent molecules from moving freely.^{112,113} Restriction must be related to the experimental parameters. When measurement times are very short, most molecules do not have enough time to reach boundaries and so they behave as if diffusing freely. Once the diffusion time increases, an increasing fraction of molecules will strike the boundaries, and diffusion will deviate

from the free, Gaussian behavior. Hence, the usual way to check for restricted diffusion is to plot the diffusion distance, calculated as for free diffusion using Einstein's equation, as a function of the square root of the diffusion time. In the case of restricted diffusion, this plot shows a curvature and finally a leveling off when the diffusion distance reaches the size of the restricting compartment. The effects of restriction will, therefore, appear in the NMR signal for diffusion times such that molecular displacements are in the order of the size of the restricting volumes. These effects will depend on the type of restriction (impermeable or permeable barriers, attractive centers, etc.), the shape of the restricting volumes (spherical, cylindrical, parallel walls, etc.), and the type of NMR experiment (constant or pulsed gradients). As a result, there is not a unique analytical expression that could describe any configuration. A simple example is represented by molecules diffusing between two impermeable parallel walls separated by a distance a .¹¹² If the theoretical, free diffusion distance greatly exceeds a , the echo attenuation A in the case of the bipolar gradient pulse experiment significantly deviates from an exponential decay and becomes independent of the diffusion time,¹¹² implying that molecules are trapped in the direction of the applied gradient:

$$A = [\sin(\gamma\delta G a/2)/(\gamma\delta G a/2)]^2 \quad (20)$$

Another interesting, but somewhat more complicated, case is represented by diffusion restricted in a spherical cavity of radius R_0 . In the limit where the theoretical, free diffusion distance largely exceeds R_0 , the attenuation is again independent of the diffusion time^{112,114} and the measured ADC decreases when the diffusion time is increased:

$$A = \exp[-(\gamma\delta G)^2 R_0^2/5] \quad (21)$$

corresponding to an asymptotic ADC value, D_{asympt} of $R_0^2/5$. The factor 5 would be replaced by 3 if diffusion was confined to the surface of the sphere.

Whatever the geometry of the restrictive medium, the deviation from linearity in the semi-log plot of the signal attenuation versus b is crucial to determine whether diffusion is restricted, although other causes may be responsible, such as diffusion in inhomogeneous systems or anisotropic diffusion. The ultimate test is to show that the measured diffusion coefficient or the signal attenuation varies when the diffusion time is changed. Such studies can theoretically lead to the determination of the geometry and size of the restricting boundaries, as with the q -space concept. To avoid restricted diffusion effects, the diffusion time must be decreased to ensure that the diffusion distance during that period remains less than the size R of the restricted region. Unfortunately, the diffusion effect in these conditions becomes small unless considerable gradient intensities are used. A further complication is that in biological tissues walls may not be reflecting boundaries but rather occur as partially absorbing borders.¹¹⁵

3.3 Permeable Barriers

When the restrictive barriers become permeable to diffusing molecules, the restricted diffusion pattern changes. The mathematical treatment of diffusion in systems partitioned by

permeable barriers is far from simple. An example was given by Tanner for equally spaced, plane barriers having a permeability constant κ .¹¹⁶ For short diffusion times, the ADC is D_0 . When the diffusion time increases, the ADC decreases, as expected for restricted diffusion, but saturates at D_{asyp} , which depends on the permeability constant:

$$D_{\text{asyp}} = D_0 / (1 + D_0 / \kappa a) \quad (22)$$

where a is the barrier spacing. This spacing can be estimated by the equivalent free diffusion distance that would be obtained from Einstein's equation with $D = (D_0 + D_{\text{asyp}})/2$ as the diffusion coefficient and $T_{d1/2}$, the corresponding diffusion time.¹¹⁷ The plot of D versus T_d then shows a typical sigmoid pattern and it becomes possible to estimate the barrier permeability κ by fitting the data with Equation (22).¹¹⁸ This approach is, however, very optimistic, as the geometrical arrangement of the medium is generally not known. In particular, this formalism does not apply to the case where the system consists of spherical cavities separated by permeable barriers.

3.4 Hindered Diffusion

True 'restricted' diffusion, which occurs in bounded media and leads to a decrease of diffusion with the diffusion time should be distinguished from 'hindered' diffusion. With hindered diffusion, diffusion is decreased by the presence of obstacles but there is no limit to the diffusion distance; consequently diffusion does not change with the diffusion time (once the hindered diffusion regime has been reached). Perhaps the most powerful concept associated with hindered diffusion is that of 'tortuosity', a concept that has been widely used in solid porous media studies and more recently in brain diffusion experiments using external tracers.¹¹⁹⁻¹²¹ The idea is that because of the presence of obstacles such as fibers, macromolecules, and organelles water molecules must travel longer paths to cover any given distance. In other words, molecules can no longer go straight from A to B, but must diffuse around structures that are impermeable to them (Figure 7). This situation results in a longer diffusion time to diffuse from A to B, or to an apparent decrease in the diffusion distance covered in a given diffusion time and in the measured ADC. This 'hindered'

Figure 7 Restricted and hindered diffusion in white matter. Several models have been suggested to explain white matter diffusion anisotropy. First, diffusion may simply be totally restricted in axons (diameter, d). Plots of diffusion distance versus diffusion time (as in Figure 8, below) however, do not support this hypothesis. One may also take into account permeability of membranes and myelin to water. Going from A to B, water molecules would have to cross several interfaces. However, one may argue that those results may also be compatible with a 'tortuosity' or 'hindrance' model, where water molecules going from A to B would have to move around fibers. As there is no limit to diffusion, this model is totally compatible with Figure 8 if extracellular water diffusion predominates

Figure 8 Plot of the diffusion distance against diffusion time in gray and white matter. The diffusion distance was obtained from the diffusion coefficient using Einstein's relation. There is no leveling off of the diffusion distance, suggesting that water diffusion is not completely restricted

diffusion effect is classically expressed quantitatively using a 'tortuosity' coefficient, λ , such that:

$$\text{ADC} = D/\lambda^2 \quad (23)$$

where D would be the diffusion coefficient observed in the absence of obstacles.

Furthermore, as there is no real barrier, molecules can, in principle, diffuse over very large distances compared with those seen in restricted diffusion. Therefore, no curvature would be seen in the plot of the diffusion distance versus the square root of the diffusion time. Similarly, the measured ADC would not depend on the diffusion time, unless the diffusion time is very short, and hindered diffusion paths would not differ significantly from free diffusion paths (Figure 8). It would then be difficult to distinguish between hindered diffusion and diffusion restricted by permeable barriers.

3.5 Anisotropic Diffusion

Diffusion in tissues may be different for different directions of motion; this anisotropy will give rise to variations in the measured diffusion coefficient with the direction of measurement. Diffusion anisotropy has been observed in muscle,⁸³ in brain white matter,^{37,56,84} (Figure 9) and, recently, in gray matter.^{122,123} It may result from restriction of diffusion inside fibers (intracellular water) or from an increased tortuosity when diffusion occurs around fibers (extracellular water). Diffusion can be both anisotropic and unrestricted. This behavior is well known in nematic liquid crystals¹²⁴ and can be found in the water lamellar phase of amphiphilic lyotropic systems.¹²⁵

Using DTI, it appears that diffusion data can be analyzed in three ways to provide information on tissue microstructure and architecture for each voxel or region of interest:¹²⁶ the mean diffusivity, which characterizes the overall mean-squared displacement of molecules (average ellipsoid size) and the overall presence of obstacles to diffusion; the degree of anisotropy, which describes how much molecular displacements vary in space (ellipsoid eccentricity) and is related to the presence of

Figure 9 Diffusion image showing anisotropic diffusion in white matter. Excellent contrast is achieved, although T_1 and T_2 effects have been removed. Corpus callosum and temporal white matter fibers, which are horizontal, are dark. Vertical corona radiata frontal fibers and internal capsule fibers are bright. In brainstem, vertical fast-conducting motor and somatosensory tracts are also bright

oriented structures; and the main direction of diffusivities (main ellipsoid axes), which is linked to the orientation in space of the structures. These three DTI 'meta-parameters' can all be derived from complete knowledge of the diffusion tensor. However because of the complexity of data acquisition and processing for full DTI, and the sensitivity to noise of the determination of the diffusion tensor eigen values, simplified approaches have been proposed.

3.5.1 Mean Diffusivity

To obtain an overall evaluation of the diffusion in a voxel or region, anisotropic diffusion effects must be avoided and the result limited to an 'invariant', i.e., a quantity that is independent of the orientation of the reference frame.^{12,86} Among several combinations of the tensor elements, the trace of the diffusion tensor,

$$\text{Tr}(\mathbf{D}) = D_{xx} + D_{yy} + D_{zz} \quad (24)$$

is such an invariant. The mean diffusivity is then given by $\text{Tr}(\mathbf{D})/3$. A slightly different definition of the trace has proved useful in assessing the diffusion drop in brain ischemia¹²⁷ (see below).

Unfortunately, the correct estimation of $\text{Tr}(\mathbf{D})$ still requires the complete determination of the diffusion tensor. Diffusion coefficients obtained by separately acquiring data with gradient pulses added along the x , y , and z axes cannot be used as these measured coefficients usually do not coincide with D_{xx} , D_{yy} , and D_{zz} , respectively. The reason is that the diffusion attenuation that results, for instance from inserting gradients on the x axis, is $A = \exp[-b_{xx}D_{xx} + 2b_{xy}D_{xy} + 2b_{xz}D_{xz}]$ and not simply $\exp[-b_{xx}D_{xx}]$ unless diffusion is isotropic (no nondiagonal terms) or there are no gradient pulses at all on the other axes (y and z , here) (no localization) during the diffusion measurement time.

To avoid this problem and to simplify the approach, several groups have designed sequences based on multiple echoes or acquisitions with tetrahedral gradient configurations to cancel nondiagonal term contributions to the MRI signal directly.^{86,128–130}

3.5.2 Diffusion Anisotropy Indices

Several scalar indices have been proposed to characterize diffusion anisotropy. Initially, simple indices calculated from DW images⁸⁴ or ADC values obtained in perpendicular directions were used, such as ADC_x/ADC_y and displayed using a color,¹³¹ scale. Other groups have devised indices mixing measurements along the x , y , and z directions, such as maximum $[ADC_x, ADC_y, ADC_z]$ /minimum $[ADC_x, ADC_y, ADC_z]$ or the standard deviation of ADC_x , ADC_y , and ADC_z divided by their mean value.¹²⁷ Unfortunately, none of these indices is really objective as they do not correspond to a single meaningful physical parameter; more importantly, they are clearly dependent on the choice of directions made for the measurements. The degree of anisotropy would then vary upon the respective orientation of the gradient hardware and the tissue frames of reference and would generally be underestimated. Here again invariant indices must be found to avoid such biases and provide objective, intrinsic structural information.¹³²

Invariant indices are made of combinations of the terms of the diagonalized diffusion tensor, i.e., the eigen-values λ_1, λ_2 , and λ_3 . The most commonly used invariant indices are the relative anisotropy, RA, the fractional anisotropy, FA, and the volume ratio, VR:

$$RA = \sqrt{(\lambda_1 - \langle \lambda \rangle)^2 + (\lambda_2 - \langle \lambda \rangle)^2 + (\lambda_3 - \langle \lambda \rangle)^2} / \sqrt{3\langle \lambda \rangle} \quad (25)$$

where $\langle \lambda \rangle = (\lambda_1 + \lambda_2 + \lambda_3)/3$

$$FA = \sqrt{3[(\lambda_1 - \langle \lambda \rangle)^2 + (\lambda_2 - \langle \lambda \rangle)^2 + (\lambda_3 - \langle \lambda \rangle)^2]} / \sqrt{2(\lambda_1^2 + \lambda_2^2 + \lambda_3^2)} \quad (26)$$

$$VR = \lambda_1 \lambda_2 \lambda_3 / \langle \lambda \rangle^3 \quad (27)$$

RA, a normalized standard deviation, also represents the ratio of the anisotropic part of $\underline{D}$ to its isotropic part. FA measures the fraction of the ‘magnitude’ of $\underline{D}$ that can be ascribed to anisotropic diffusion. FA and RA vary between 0 (isotropic diffusion) and 1 ($\sqrt{2}$ for RA) (infinite anisotropy). As for VR, which represents the ratio of the ellipsoid volume to the volume of a sphere of radius $\langle \lambda \rangle$, its range is from 1 (isotropic diffusion) to 0; as a result some authors prefer to use $(1 - VR)$.¹³³

Once these indices have been defined, it is possible to evaluate them directly from DW images, i.e., without the need to calculate the diffusion tensor.¹³⁴ For instance, A_σ which is very similar to RA, has been proposed as:¹³⁵

$$A_\sigma = \sqrt{\sum_{i=x,y,z} (D_{ii} - \langle D \rangle)^2 + (D_{xy}^2 + D_{xz}^2 + D_{yz}^2) / \sqrt{6} \langle D \rangle} \quad (28)$$

with $\langle D \rangle = \sum_{i=x,y,z} D_{ii} / 3$.

For list of General Abbreviations see end-papers

Also, images directly sensitive to anisotropy indices, or anisotropically weighted images, can be obtained.¹³⁶ Finally, the concept of these *intravoxel* anisotropy indices can be extended to a family of *intervoxel* or ‘lattice’ measures of diffusion anisotropy, which allows neighboring voxels to be considered together, in a region of interest, without losing anisotropy effects resulting from different fiber orientations across voxels.¹³³ Clinically relevant images of anisotropy indices have been obtained in the human brain (Table 1).^{41,137}

3.5.3 Fiber Orientation Mapping

The last family of parameters that can be extracted from the DTI concept relates to the mapping of the orientation in space of tissue structure. The assumption is that the direction of the fibers is colinear with the direction of the eigen-vector associated with the largest eigen-diffusivity. This approach opens a completely new way to obtain directly in vivo information on the organization in space of tissues such as muscle, myocardium, and brain or spine white matter, which is of considerable interest, clinically and functionally. Direction orientation can be derived from DTI directly from diffusion/orientation-weighted images or through the calculation of the diffusion tensor. A first issue is to display fiber orientation on a voxel-by-voxel basis. The use of color maps was first suggested,¹³¹ followed by representation by ellipsoids,^{12,133} octahedra¹³⁸ or vectors pointing in the fiber direction.^{139,140} A second issue is to assess connectivity from DTI data in order to visualize anatomical connections between different parts of the brain on an individual basis. Studies of neuronal connectivity are tremendously important to the interpretation of functional MRI data and for establishing how activated foci are linked together through networks.^{141,142} This issue is difficult, as continuity of fiber orientation from voxel to voxel has to be inferred. Fiber orientation may appear to be varying because of the occurrence of noise in the data. In a given voxel fibers may be merging, branching or dividing. In addition, several fascicles may cross in a given voxel, which cannot be detected with the diffusion-tensor approach in its present form. Structures that exhibit anisotropic diffusion at the molecular level can be isotropically oriented at the microscopic level, resulting in a ‘powder average’ effect that is difficult to resolve.¹⁴³ The semilog plot of the signal attenuation versus b may not be linear in this case.¹²⁵ This deviation from linearity can be ascribed to anisotropy and not to restricted diffusion because the diffusion measurements are independent of the diffusion time. Several groups have recently approached the difficult problem of inferring connectivity from DTI data in the rat brain¹⁴⁴ in vitro and in the living human brain¹⁴⁵ (Figure 10).

3.6 Diffusion in Multiple Compartment Systems

Most diffusion measurements in biological tissues refer to an ADC and yet it is generally considered that diffusion in the measurement volume (voxel) has a unique diffusion coefficient. This simplification may not always be legitimate, since partial volume effects may occur and most tissues are made of multiple subcompartments (with at least intracellular and extracellular components). Assuming measurement times are short and diffusion is unrestricted in each subcompartment i , and that there is no exchange, the signal attenuation is:

$$A = \sum_i \rho_i \exp(-bD_i) \quad (29)$$

where ρ_i is the density of molecules diffusing in compartment i , and D_i the associated diffusion coefficient. In this case, the ADC that would be measured would depend on the range used for the b values and would not reflect properly the diffusion in the voxel. Measurements with low b values would then be

more sensitive to fast diffusion components. The ideal approach would be to separate all subcompartments by fitting the data with a multiexponential decay. Unfortunately, the values for D_i are often low and not very different from each other; consequently very large b values and very high SNR would be required.

Relaxation effects must also be considered if compartments have different relaxation rates.¹⁴⁶ If all spins do not have the same transverse relaxation during the pulse sequence, Equation

Figure 10 Diffusion tensor imaging and fiber orientation mapping in the brain of a normal volunteer at 1.5 T. The direction of the white matter fibers can be determined from the eigen vectors of the diffusion tensor for each voxel and superimposed on a 3D rendering of internal brain structures. (Contribution of J.F. Mangin, C. Clark, C. Poupon, D. Le Bihan)

(5) must be complemented with a decay term:¹¹⁵

$$\partial P(z_2, z_1 t) / \partial t = D \nabla^2 P(z_2, z_1 t) - P(z_2, z_1 t) / T_2 \quad (30)$$

For two compartments, assuming measurement times are short and, therefore, exchanges are small, the diffusion signal is given by:

$$S = F_1 \exp(-bD_1) + F_2 \exp(-bD_2) \quad (31)$$

where b is the sequence diffusion factor, D_1 , D_2 are the diffusion coefficients and F_1 , F_2 are relative weights to the signal of the two compartments. Estimates of F_1 , F_2 and D_1 , D_2 are obtained by fitting a series of signals acquired with multiple b values. For a spin echo sequence with $TR \gg T_1$, F depends on the volume fraction f and the relaxation time T_2 of each compartment:

$$F = f \exp(-TE/T_2) \quad (32)$$

Two diffusion compartments have been found in the rat brain.¹⁴⁷ Assignment of these compartments to extra- and intracellular water is not, however, straightforward, as the values found for F_1 and F_2 are apparently opposite to the known volume fractions for the intra- and extracellular spaces (82.5% and 17.5%, respectively). A first explanation for this discrepancy is that T_2 effects must be taken into account when converting F values into f values. A second factor is that the exchange rate may not be negligible. It has been shown that if the residence rate in each compartment is considered, the contribution of the fast diffusing component is overestimated.¹⁴⁸ It is, therefore, not yet certain that the two compartments that have been observed do correspond to the intra- and extracellular compartments.

The situation is even more complex when measurement times are longer. First, restricted diffusion may be seen in the smallest subcompartments. Second, molecular exchanges may occur between communicating compartments. As a result, the analytic treatment becomes difficult. Applying the central limit theorem for statistically distributed compartments in the case of long diffusion times, the use of a single apparent diffusion constant D_a can be justified:

$$D_a = \sum_i \rho_i D_i \quad (33)$$

This result is also consistent with NMR dispersion studies,¹⁰² which consider that cell membranes can be ignored on the NMR time scale. In intermediate situations, the geometrical arrangement and the diffusion coefficients of each compartment must be considered as well as their rates of exchange.¹⁴⁹ The comprehensive analysis of the diffusion attenuation curves obtained with different diffusion times may lead to an accurate description of the medium microstructure.

It is clear that the ADC depends on the range used for the b values and would not reflect properly diffusion in the tissue. Measurements with low b values (less than 1000 s mm^{-2}) would be more sensitive to fast diffusion components, such as those occurring in the extracellular compartment. In clinical studies and most animal experiments, especially when data are fitted to a single exponential, diffusion patterns observed in tissues have to be explained by features of the extracellular

space, although this compartment is physically small. Changes in the ADC calculated in these conditions should be interpreted in terms of changes in the diffusion coefficient of the extracellular space (tortuosity) and in its fractional volume relative to the intracellular volume. This explains why diffusion has appeared as a sensitive marker of the changes in the extracellular/intracellular volume ratio, as observed in brain ischemia, spreading depression,^{80–82} status epilepticus,⁷⁸ or extraphysiological manipulations of the cell size through osmotic agents.¹⁵⁰ Using large b values, it becomes increasingly possible to assess separately the intra- and extracellular compartments and their relative volumes in vitro¹⁵¹ and in vivo, as attempted in the rat brain¹⁴⁷ and the human brain.¹⁵²

3.7 Metabolites

Data on magnitudes and even directional anisotropy of diffusion coefficients of molecules such as choline, creatine/phosphocreatine and NAA in animals,^{97,153,154} and human brain⁹⁵ have been made available. Although diffusion rates of metabolites in pure water are lower than that of water because of the difference in molecular weight and hydration layers, the ADC values of these metabolites in brain are considerably smaller. Typical values from a series of 10 normal volunteers (18 cm^3 voxels located in white matter, diffusion time 240 ms) are $0.13 \times 10^{-3} \text{ mm}^2 \text{ s}^{-1}$ for choline and creatine and $0.18 \times 10^{-3} \text{ mm}^2 \text{ s}^{-1}$ for NAA compared with $1.24 \times 10^{-3} \text{ mm}^2 \text{ s}^{-1}$ for choline and $0.85 \times 10^{-3} \text{ mm}^2 \text{ s}^{-1}$ for NAA at 35°C in vitro.¹⁵⁵ The fact that metabolites, as well as molecules such as fluorodeoxyglucose 6-phosphate,¹⁵⁶ with different molecular weights had very similar ADC values in vivo is striking and remains to be explained. The very low values of the ADC obtained with long diffusion times are, of course, compatible with restriction of these metabolites in compartments that were about the same size. For instance, recent experiments varying the diffusion times have shown that diffusion of NAA is considerably restricted in a manner compatible with two compartments, one of $7\text{--}8 \text{ }\mu\text{m}$ and one of approximately $1 \text{ }\mu\text{m}$, possibly representing the cell bodies and the intra-axonal space.¹⁵⁷ However, intracellular obstacles may also play an important role, as water molecules could diffuse easily in small spaces between small obstacles, such as mitochondria, organelles or macromolecules, while larger metabolites would ‘feel’ a more obstructed medium. Tortuosity factors may, therefore, be larger for metabolites than for water and this would explain, at least partially, the diffusion decrease for intracellular metabolites that has been observed during ischemia.^{158,159}

3.8 Summary: Application to Brain White Matter

The concepts of restriction, hindrance, tortuosity, and multiple compartments are particularly useful to understand diffusion findings in brain white matter. Water diffusion is highly anisotropic in white matter^{37,56,84} and this anisotropy is observed even before fibers are myelinated, though at a lesser degree.^{137,160–166} ADC values obtained by measurements made parallel and perpendicularly to the fibers do not seem to depend on the diffusion time^{167,168} at least for diffusion times longer than 20 ms (see Figure 8).

Initial reports suggested that the anisotropic water diffusion could be explained by restriction of the water molecules to the axons (anisotropically restricted diffusion) by the myelin sheath.^{169,170} However, although restricted diffusion has been seen for intra-axonal metabolites, such as NAA, or for truly intra-axonal water,¹⁷¹ it now appears that most studies were performed with relatively low b values and are mostly sensitive to the extracellular, interaxonal space. In this condition, diffusion anisotropy in white matter should be linked to the anisotropic tortuosity of the interstitial space between the fibers: diffusion would be more impeded perpendicular to the fibers because of their geometric arrangement (Figure 7).¹⁶⁷

Considering a bundle where fibers are organized in the most compact way, molecules would have to actually travel over a distance of $\pi d/2$, where d is the fiber diameter, for an apparent diffusion distance equal to the fiber diameter. Therefore, on average, the ADC measured perpendicularly to the fibers would be reduced, whatever the diffusion time, to:

$$\text{ADC} = (2/\pi)^2 D_0 \approx 0.4 D_0 \quad (34)$$

where the reference value, D_0 , is the diffusion value measured parallel to the fibers. This ratio of about 0.4 fits reasonably very well with literature data,¹⁶⁷ although much larger ratios have been reported.¹³³ This rough model also implies that the tortuosity factor would be anisotropic in white matter with a $\lambda_{\text{perpendicular}}/\lambda_{\text{parallel}}$ ratio of $\pi/2$ (≈ 1.57). Unfortunately no systematic measurements of λ have yet been made in white matter using ionic extracellular tracers,^{2,119} although anisotropy has been seen.¹⁷² Another interesting point about this model is that it is compatible with the fact that no true restricted effects are observed when the diffusion time is increased, as there are no actual boundaries to diffusing molecules. Also, the parallel organization of the fibers may be sufficient to explain the presence of anisotropy before myelination. However, as the axonal membranes should be more permeable to water than the myelin sheaths, the degree of anisotropy should be less pronounced in the absence of myelin, as significant exchanges with the axonal spaces should occur. Oriented filaments within the axoplasm do not seem to play an important role.¹⁷³ Fiber orientation mapping and connectivity studies derived from anisotropic diffusion in white matter will clearly benefit from a better understanding of the respective contributions of intra-axonal and extra-axonal compartments to anisotropy mechanisms.¹⁷⁴

4 CLINICAL APPLICATIONS

Diffusion imaging is a truly quantitative method. The diffusion coefficient is a physical parameter that directly reflects the physical properties of the tissues in terms of the random translational movement of the molecules under study (most often water molecules, but sometimes metabolites). The diffusion coefficient does not depend on the field strength of the magnet or the pulse sequence used, which is not the case for the other classical MRI parameters such as T_1 or T_2 . Diffusion coefficients obtained at different times in a given patient, or in different patients, or in different hospitals can be compared without any need for normalization.

4.1 Central Nervous System

The most clinically relevant field of application of diffusion MRI is in the nervous system. Diffusion MRI has already appeared as a breakthrough in two areas: early brain ischemia and white matter diseases.

During the acute stage of brain ischemia, water diffusion is decreased in the ischemic territory by as much as 50%, as shown in cat brain models.¹⁷⁵ This diffusion slowdown is linked to the cytotoxic edema that results from the energetic failure of the cellular membrane Na^+/K^+ pumping system. The exact mechanism by which diffusion is reduced is still unclear (increase of the slow-diffusion intracellular volume fraction, changes in membrane permeability,¹⁷⁶ or shrinkage of the extracellular space resulting in increased tortuosity for water molecules.^{177,178} have been suggested). Diffusion MRI has been extensively used in animal models to establish and test new therapeutic approaches. These results have been confirmed in patients with stroke, offering the potential to highlight ischemic regions within the first hours of the ischemic event, when brain tissue might still be salvageable,^{179,180} well before conventional MRI becomes abnormal (vasogenic edema). Combined with perfusion MRI, diffusion MRI is under clinical evaluation as a tool to help clinicians to optimize their therapeutic approach to individual patients,¹⁸¹ to monitor patient progress on an objective basis, and to predict clinical outcome.^{182–185}

In white matter, DTI has already shown its potential in diseases such as multiple sclerosis^{186–188} leukoencephalopathy,¹⁸⁹ Wallerian degeneration, Alzheimer disease,^{190,191} and Creutzfeldt-Jacob disease.^{192–194} Mean diffusivity indices, such as the trace of the diffusion tensor, reflect overall water content, while anisotropy indices indicate myelin fiber integrity. It has been shown that the degree of diffusion anisotropy in white matter increases during the myelination process,^{137,162,195} and diffusion MRI could be used to assess brain maturation in children,¹⁹⁶ newborns, or premature babies.^{137,197} Abnormal connectivity in frontal white matter based on DTI data has also been reported in schizophrenic patients.¹⁹⁸ The potential of diffusion MRI has also been studied in brain tumor grading,^{199–201} trauma,²⁰² hypertensive hydrocephalus,²⁰³ AIDS,²⁰⁴ eclampsia,²⁰⁵ leukoaraiosis,^{206,207} and the spinal cord.^{87,185,208,209}

4.2 Body

The use of diffusion imaging has been less successful in areas of the body apart from the brain because of the occurrence of strong respiratory motion artifacts and of the short T_2 values of body tissues, which require shorter TE than in the brain and, therefore, leaves less room for the diffusion gradient pulses. These obstacles, however, can sometimes be overcome with ad hoc MR sequences and hardware. Potential for tissue characterization has been shown in the extremity muscles,²¹⁰ the spine,^{211,212} the breast,^{54,213,214} the kidney, and the liver.^{215–218} Muscle fiber orientation can be approached using DTI in organs such as the tongue²¹⁹ or the heart. Myocardium DTI^{220,221} has tremendous potential for providing data on heart contractility, a very important parameter, but remains technically very challenging to perform in vivo because of heart motion. Other applications include temperature imaging

through the sensitivity of diffusion coefficients to temperature.^{107,108,210,222}

5 CONCLUSION

Many tissue features at the microscopic level may influence NMR diffusion measurements. So far, many theoretical analyses of the effect of restriction, membrane permeability, hindrance, anisotropy, or tissue inhomogeneity have been published. These analyses underline how much care is necessary to conduct diffusion NMR studies properly and to interpret the results. Although the results of these analyses have been applied to characterize nonliving systems, such as porous media, much work remains to be done to produce accurate information on microstructure and microdynamics in vivo in biological systems. Powerful tools, such as diffusion spectroscopy of metabolites, DTI or *q*-space imaging, that are still under development are expected to provide such information.

Biographical Sketch

Denis Le Bihan. b 1957. Ph.D., 1987, Physics, M.D., 1984, Radiology, University of Paris, France. Former Chief of the Radiology Research Section, Clinical Center, NIH, Bethesda, USA. Presently Research Director, French Atomic Energy Commission, Director, Anatomical and Functional Neuroimaging Laboratory, Orsay, France, and Clinical Professor of Radiology, Harvard University, Cambridge, USA. Corresponding Member, French Academy of Sciences. Approx. 400 articles, book chapters, abstracts and patents. Research interests: diffusion, perfusion and functional MRI.

Brain MRS of Human Subjects

James W. Prichard

Yale University, New Haven, CT, USA

1 INTRODUCTION

A biomedical revolution based on NMR technology is under way. Many of the NMR methods described in this Encyclopedia are already in use for medical research and diagnosis, and many others will find such application soon. As the full impact of mature NMR methods becomes evident in the latter 1990s, it will be measured on the same scale with such things as microscopy and genetics. Two well-established characteristics of biomedical NMR technology ensure this outcome: it is remarkably noninvasive (see *Health and Safety Aspects of Human MR Studies*) and it is remarkably versatile, as attested in many other chapters. In each respect separately, it exceeds most other technologies available for the study of living tissue. By their combination, it stands alone.

This chapter deals with human brain research done by the branch of biomedical NMR technology designated magnetic resonance spectroscopy (MRS) to distinguish it from magnetic resonance imaging (MRI), which makes pictures of anatomical structure from the water proton signal. MRS obtains chemically specific information from biological tissue by the measurement of much smaller signals from ^1H , ^{31}P , ^{13}C , ^{17}O , and other magnetic nuclei in a variety of compounds. It is extending the range of biomedically useful NMR measurements to practical applications that would have courted dismissal as visionary a decade ago. In 1994, signals from more than two dozen compounds can be detected routinely in the human brain, and many more are in prospect. All report on biochemical phenomena previously accessible only by surgical removal of tissue or at autopsy. As various forms of MRS supported by MRI reach technical maturity, their collective contributions to an understanding of normal and deranged biochemistry in the brain will amount to nothing less than a new neurobiological discipline comparable in scope to today's neurochemistry, neuroanatomy, and neuropathology combined. All stages of normal human brain development and disease processes—including intrauterine stages—will be open to inspection along the many axes MRS can measure.

The MRS studies mentioned in this chapter are intended to help scientists and physicians interested in the brain to evaluate the above assertions, which may appear extravagant to readers who are exploring modern NMR for the first time. Many more studies appropriate for that purpose have been published than can be cited. Selection among them was intended to favor efforts that illuminate each other or set new problems by failing to do so, but it cannot have escaped all of the author's biases.

2 ^1H AND ^{31}P SPECTRA

Most human brain MRS research to date has used these two nuclei. Figures 1 and 2 illustrate the normal features and some disease-related abnormalities of brain ^1H and ^{31}P spectra with simulations that are free of the wide technical variation among spectra in original publications. Differences in acquisition parameters and data processing can cause spectra that are biologically equivalent to look quite different from each other. For readers new to either NMR or neuroscience, the variation can easily distract attention from features of biological importance.

The simulated spectra in Figures 1 and 2 were generated by Mathematica[®] and annotated in Adobe Illustrator[®]. Within each figure, random noise is of the same intensity in all spectra. Resonance variables were adjusted to mimic the appearance typical of many published spectra, in which less intense resonances are not evident because of such factors as long spin echo times, J coupling, and processing methods. The resonances shown are usually identifiable in all spectra from normal adult brain. The disease-related variations are large ones that have been reported by more than one group. They are presented together to emphasize their potential for metabolic fingerprinting of different disease processes.

3 NORMAL BRAIN FUNCTION: LACTATE IN HUMAN SENSORY SYSTEMS

A signal from lactate is detectable in ^1H spectra from the normal human brain.¹ Stimulation of the human visual²⁻⁴ and auditory⁵ systems can cause increases in lactate observable by ^1H MRS in the primary cortical receiving areas. These findings are consistent with positron emission tomography (PET) data showing that similar stimulation can increase glucose uptake more than oxygen extraction in the regions affected.⁶ The PET workers interpreted their observations as evidence for preferential activation of nonoxidative glycolysis. The MRS data strengthen that view.

The notable aspect of this research area is the evidence from at least five different PET and NMR groups showing that glycolysis can increase more than respiration in response to some kinds of activation within the normal range of brain function. The phenomenon is well known in skeletal muscle. Selective activation of muscle cells with differing capacities for glycolysis and respiration is a normal feature of muscle function, and heterogeneous distribution of glycolytic and respiratory enzymes has long been employed for histochemical characterization of individual muscle cells. Evidence for similarly heterogeneous enzyme distribution already exists at the level of cell groups in the animal brain.⁷ Like muscle cells, neurons and possibly glia may well have variable capacity for glycolysis and respiration related to their physiological functions.

These PET and MRS data prompt the question of what adaptive utility lactate elevation resulting from brain activity might have. Two novel possibilities that can be tested by experiment are the following:

(1) *Lactate may be a local energy storage medium that is increased in anticipation of sudden high energy demand.* Ammunition stacked beside cannons defending a fort is more useful than ammunition in a remote storehouse if the fort is

Figure 1 Simulated ^1H spectra from brain, created in Mathematica[®] and annotated in Adobe Illustrator[®]. Alterations typically caused by six pathological conditions are contrasted with each other and to normal. Spectral variables were adjusted to mimic the appearance common in published spectra. Random noise and each unfilled resonance are of the same intensity in all spectra. The 'normal' spectrum represents resonances from choline-containing compounds (cholines), creatine and phosphocreatine (creatines), *N*-acetyl-containing compounds, mostly *N*-acetylaspartate (*N*-acetyls), and lactate methyl protons (lactate). Glutamate and glutamine signals are represented as unresolved low-intensity resonances between 2 and 3 ppm. The 'pathological' spectra were created by varying the intensities of signals reported to be affected by the disease states indicated by labels on each spectrum. The abnormalities shown are the ones most often associated with each condition, but they are not all present in every case. The elevated lactate signal in four spectra displays the characteristic 7 Hz splitting caused by *J* coupling to the C-2 proton

suddenly attacked. Suspicion of imminent attack would certainly cause the fort's defenders to move extra ammunition from the storehouse to the cannons, to shorten the response time and lengthen the duration of maximum firing. In the brain, neurons can suddenly be called upon to fire hundreds of action

potentials a second and surrounding cells to recycle transmitter at proportional rates. The immediate metabolic burden of this intense activity falls principally on synaptic terminals, which are quite small and in consequence have low ratios of cytoplasmic volume to the area of excitable surface membrane that they must support. In such a structure, the Krebs cycle can respond to sudden maximum energy demand more quickly if it is not limited by the time necessary for activation of glycolysis, which is long on the scale of intense neuronal discharge and transmitter release. Local lactate elevation by previous activity would prime synaptic terminals to deliver their maximum response to sudden demand while glycolytic rate is increasing. Existing techniques for the measurement of glucose and oxygen uptake and lactate concentration would not detect most instances of this process, because the ones that can be used in vivo, including MRS, report on overall changes in volumes of tissue much larger than the scattered locations at which such priming would ordinarily occur, and the others are bedeviled by the possibility of agonal artifact. Only when it occurs in many cells at the same time—as during sensory barrages and seizure discharge—could such a process be detected by present methods.

Figure 2 Simulated ^{31}P spectra from normal and diseased brain, created and presented by the same procedures used for Figure 1. The resonances represented are from phosphomonoesters (PME), inorganic phosphate (Pi), phosphodiester (PDE), phosphocreatine (PCr) and the α , β , and γ phosphates of adenosine triphosphate (ATP). In the 'stroke - severe' example, all of the signal present is Pi, indicating total loss of high-energy phosphate compounds

(2) *Lactate may have a signaling function in the brain.* Lactate is well suited to be a neuromodulator—a substance which alters the excitability of local neural ensembles. It is produced at increased rates whenever glycolysis accelerates in response to neural activity. It accumulates during pathological activation caused by ischemia or lack of oxygen, and, as described above, during some kinds of activation in the physiological range. If—upon escape from the active cell that produced it—it reduced the excitability of adjacent cells, it could both inhibit seizure discharge and ‘sharpen’ transmission along multifiber pathways, a process known to occur by other mechanisms. A finding consistent with this idea is available: in *Torpedo* electropex, lactate in concentrations that can be produced by brain activation inhibited release of acetylcholine.⁸

4 STROKE

Stroke is the commonest major brain disease and a principal medical burden on society through the lost productivity it causes and its consumption of resources by extended disability. It is a natural place to test the benefits of new biomedical technology.

MRS observations on human stroke are far enough advanced to allow initial assessment of the role MRS will come to have in patient management. Lactate and *N*-acetyl (NA) resonances in the ¹H spectrum and intracellular pH (pHi) derived from the ³¹P spectrum appear to have the best prospects for clinical utility.

4.1 ¹H MRS in Stroke

Figure 1 illustrates the kind of change commonly observed in ¹H spectra of human brain infarction: loss of the NA signal and elevation of the signal from lactate. Loss of NA signal should ensue from death of neurons, which are the only cells in mature brain thought to contain *N*-acetylaspartate (NAA), the principal source of the NA resonance. The NA signal was depressed both in the first few days after stroke onset and several weeks later in six patients studied at least twice.⁹ In 10 patients studied within 60 h of stroke onset, it was reduced relative to the homologous region of the contralateral hemisphere in all but two; in seven of the same patients, repeat examination 1–2 weeks later showed additional decline at an overall rate calculated at $-29\% \pm 9\%$ per week.¹⁰ Similar findings have been reported by other groups.^{11–13}

Decline of the NA signal in the first days after a stroke surely reflects, in part, clearing of debris from neurons killed at the outset, but it may also be evidence of continuing neuronal loss after the acute period, possibly in the ischemic penumbra.¹⁴ Therapy which prevents delayed neuronal loss would presumably also reduce eventual fixed deficit. Monitoring of the NA signal may prove useful as a surrogate endpoint for evaluation of therapies intended to reduce continuing neuronal loss in the subacute period.

Lactate elevation by acute infarction is readily detectable by ¹H MRS (Figure 1). However, the first report of increased lactate associated with stroke¹⁴ was on patients studied months after the stroke occurred. Many observers including

the present writer doubted that stroke-associated lactate elevation would persist so long, but subsequent observations by several groups have shown that it does. Serial study of individual patients demonstrated continuous lactate elevation for weeks after stroke in most and for several months in some.⁹ Again, similar observations have been made by other groups.^{11–13}

Multiple mechanisms of lactate elevation must be at work over so long a period. A newly infarcted region of brain accumulates lactate to a concentration of 15–30 mM within minutes of losing its blood supply, as glucose and glycogen in unperfused tissue are metabolized in the absence of oxygen, which is exhausted in the first few seconds. If the region is never reperfused, the lactate in it can dissipate only by diffusion, but the process would not take weeks to months in the presence of active tissue repair processes. Other possible sources of elevated lactate associated with infarction include adjacent regions of surviving but impaired tissue referred to as an ‘ischemic penumbra’,¹⁵ infiltrating cells involved in the tissue’s reaction to injury, and altered metabolism of surviving brain. MRS has provided evidence for the second of these:¹⁶ the brain of a patient studied two weeks after a stroke and autopsied a week later had large numbers of macrophages in the regions where ¹H MRS had shown elevated lactate. The role of altered metabolism is conjectural at present; the long-term metabolic response of brain tissue that survives ischemic insult is not well understood.

Lactate that accumulates in the killed core of an infarct is metabolically inert, while that in an ischemic penumbra turns over, albeit probably at a rate different from that of normal brain tissue. The anatomical boundary between pools of lactate in these two states need not be sharp; the pools may even be anatomically interdigitated. Their relative sizes reflect the proportion of killed to surviving tissue early in the history of the lesion, and may therefore indicate how a particular lesion is likely to evolve. An advanced form of combined ¹H/¹³C MRS that has been shown to be feasible in humans can make a pertinent measurement. Inert and metabolically active lactate associated with a human stroke can be distinguished from each other by determining how much of the total stroke-associated lactate pool can be labeled with ¹³C from blood glucose. Explanation of this remarkable possibility requires a brief description of the NMR properties of ¹³C.

4.2 ¹³C MRS

Carbon in Nature is nearly 99% ¹²C, which is not magnetic and hence gives no NMR signal. The stable magnetic isotope ¹³C is 1.1% naturally abundant. Its potential for biological studies was appreciated early in the second decade of empirical NMR work. In 1958, the following passage was written by P. C. Lauterbur:¹⁷

‘Most practical applications of ¹³C spectra must await some improvement in the signal-to-noise ratio. *One application that might be made immediately is in the use of ¹³C as an isotopic tracer in reactions.* Various chemical forms of carbon could be identified by their chemical shifts and fine structures, even in complex mixtures, after the introduction of a compound enriched in ¹³C. *Even some biological systems might be studied by this technique.*’ (Emphases added.)

These words are the conceptual origin of biomedical ^{13}C MRS. In 1957, their author had published the first report of ^{13}C chemical shifts,¹⁸ which was followed shortly by another.¹⁹ Years became decades while NMR technology evolved to a stage at which Lauterbur's idea could be explored by ^{13}C labeling studies, first on enzyme systems and functioning cells,²⁰ later on intact animal liver,²¹ animal brain,²² and human brain.^{23,24} The potential adumbrated by these studies is so great that even the most advanced of them belong to what later generations of biomedical scientists will regard as the early history of ^{13}C MRS. Lauterbur was remarkably prescient.

In living subjects including humans, natural abundance ^{13}C MRS has much still unexploited potential for characterization of normal and pathological variation among tissues, but the most inviting opportunity that ^{13}C MRS presents to biomedical workers is ^{13}C enrichment of molecules observable in vivo. As demonstrated more than two decades ago in *Candida utilis*,²⁵ feeding a ^{13}C -enriched nutrient to a living organism provides the simultaneous advantages of increased signal-to-noise ratio for observation of molecules that receive the ^{13}C through metabolic processes and a nondestructive means of measuring the rates of those processes. The adult brain normally derives nearly all of its energy from glucose, most of which it converts to two molecules of lactate; if the glucose was enriched in ^{13}C at the C-1 position, one of the lactates receives ^{13}C glucose in its methyl position. Further metabolism in the Krebs cycle creates several other ^{13}C -labeled molecules observable in vivo, the most prominent of which is 4- ^{13}C -glutamate. After animal experiments demonstrated that 1- ^{13}C -glucose, 3- ^{13}C -lactate, and ^{13}C -labeled amino acids could be detected in living brain by ^{13}C MRS,²² similar observations were made in the human.²⁴

4.3 Detection of ^{13}C by ^1H MRS

Direct ^{13}C MRS has the disadvantage for in vivo work of long acquisition times due to the low sensitivity of ^{13}C compared to ^1H . In samples containing enough ^1H - ^{13}C bonds, the presence of the ^{13}C can be detected in ^1H spectra by the characteristic way in which it splits the signal from protons bonded to it. Exploitation of this phenomenon confers proton sensitivity on NMR measurement of ^{13}C in some positions of intact, functioning molecules. The principle was used in studies of organic molecular structure as early as the 1960s.²⁰ Later, technological advances and diligent effort allowed its successful adaptation to observation of ^{13}C -labeled compounds in the brains of living animals²⁶ and humans.²³ By the use of appropriate models, cerebral metabolic rates can be calculated from the time course of ^{13}C accumulation in observable metabolic pools.²⁷ These and related NMR methods are still in the early stages of development; in their fully mature forms, they are likely to be the preeminent means of measuring metabolic rates in the living human brain.

4.4 Labeling of Stroke-Elevated Lactate with ^{13}C

In stroke, ^{13}C labeling can make the important distinction between lactate which is trapped in a nonmetabolizing compartment and lactate that is persistently elevated in the presence of competent metabolic machinery. This strategy was used to show that shock-elevated lactate in rabbit brain²⁸ is all metabo-

lically active,²⁹ and it is equally applicable to assessment of stroke-elevated lactate in the human, as has been demonstrated.³⁰

However, the prospect for the routine use of this very sophisticated technique in emergency stroke evaluation depends on other things. Carbon-13 labeling of the kind described can certainly provide information about how much of a fresh stroke is an ischemic penumbra,¹⁴ but rapid evolution of MRI may provide equivalent information from simpler measurements. The best candidates are diffusion weighted imaging (DWI)³¹ (see *Diffusion: Clinical Utility of MRI Studies*) and magnetization transfer contrast imaging (see *Magnetization Transfer Contrast: Clinical Applications*). The point here is that if ^{13}C labeling of stroke-elevated lactate proves to be a sufficiently novel predictor of a fresh infarct's later course to justify its relative complexity, its minor risk, and a few hundred dollars for each patient, it can be widely implemented.

4.5 ^{31}P MRS in Stroke

Figure 2 illustrates two degrees of loss of energy stores and elevation of inorganic phosphate that can be caused by stroke. Intracellular acidosis is measurable from the resonant frequency of the inorganic phosphate signal, but the frequency difference is too small to be evident in the figure.

The first ^{31}P MRS study of human stroke found normal metabolite ratios with reduced total phosphorus signal in chronic stroke, consistent with the replacement of infarcted tissue by cerebrospinal and interstitial fluid.³² After developing the capability to study acutely ill patients in a magnet—a decidedly nontrivial achievement—a group at Henry Ford Hospital in Detroit used it to monitor ^{31}P changes from the acute to the subacute period.³³ Phosphocreatine and ATP were reduced in the acute period, and inorganic phosphate was elevated, as shown in Figure 2. Intracellular pH was acidotic. All of these changes are consistent with the traditional understanding of stroke pathophysiology, but they did not correlate well with clinical measures. Alkalosis replaced acidosis within a few days. The authors suggested that effective therapy might have to be instituted during the period of acidosis.

An estimate of tissue Mg^{2+} concentration can be made from information in ^{31}P spectra.³⁴ In stroke, Mg^{2+} was elevated in the acidotic period; it might be a pathophysiological factor or a marker of cellular injury.³⁵

^1H and ^{31}P spectra can both be obtained in the same session. Combined $^1\text{H}/^{31}\text{P}$ observations are a powerful way of analyzing relationships among a wide range of brain metabolites, as was first demonstrated in animal work on hypoglycemia.³⁶ Despite rather considerable technical obstacles to doing this in human stroke patients, two groups have accomplished it,^{37,38} and the results are illuminating. Both groups found that stroke-associated lactate and pH were usually not inversely correlated. In combined $^1\text{H}/^{31}\text{P}$ observations ranging from the acute to the chronic period, the more common association was of elevated lactate with alkalosis, rather than acidosis or normal pH. Because ^{31}P and ^1H spectra come from tissue volumes that are not the same size and are both large compared with the dimensions of any of the several metabolic compartments they contain, MRS-observable metabolites should not be expected to behave as though they were in a well-stirred test tube. Dissociation of lactate from pH has been observed in ex-

perimental status epilepticus by NMR³⁹ and, by biochemical techniques, in tumors and one day after global ischemia.⁴⁰

5 EPILEPSY

5.1 ³¹P MRS in Epilepsy

Several animal studies on seizure phenomena in the early years of in vivo MRS demonstrated that the PCr/Pi (Figure 2) decline well established by traditional biochemical research could be observed in the the living brain.⁴¹ Due to the limited bore size of available spectrometers, the first MRS observations on the epileptic human brain were ³¹P spectra from infants.⁴² Findings during seizures were as expected: the PCr/Pi ratio was decreased about 50%, as shown in Figure 2, and it returned to normal after seizure discharge ceased. Infants who had the lowest ratios during seizures developed long-term neurological sequelae.

The development of spectrometers with bores large enough for adults was quickly followed by studies of chronic temporal lobe epilepsy, which is a major problem in modern epilepsy management. Two groups have published data on enough patients to allow comparison of results, which are somewhat different. One found alkaline pH_i associated with the seizure focus in eight patients, seven of which also had increased Pi and decreased PME.^{43,44} The other group reported low PCr/Pi ratios without other changes.⁴⁵ Further work will be necessary to determine whether the discrepancy reflects technical factors of differences between patient populations.

5.2 ¹H MRS in Epilepsy

The principal component of the NA signal in ¹H spectra of normal brain is from NAA, which occurs mainly if not exclusively in neurons. Reduction of the NA signal implying loss of neurons is a common feature of chronically epileptogenic brain tissue, having been documented in two papers,^{46,47} and in six preliminary reports by these groups and others at the Annual Meeting of The Society of Magnetic Resonance in Medicine in 1993. The phenomenon is illustrated in Figure 1.

These data have the important implication that chemically specific ¹H MRS abnormalities may be detectable in vivo before structural changes in patients with chronic temporal lobe epilepsy, which is commonly associated with a neuropathological state known as mesial temporal sclerosis and can often be relieved by surgery. MRI techniques that appear to be especially sensitive to this pathology have been reported,^{48,49} but even if they become routine, noninvasive preoperative detection of chemical abnormality is likely to improve accurate selection of the tissue to be resected for relief of complex partial epilepsy. MRS will be especially important for that purpose if the NA signal proves to be the first NMR quantity to change as mesial temporal sclerosis develops. Noninvasive electroencephalographic and NMR techniques together may soon eliminate the need for implantation of intracranial electrodes to determine which patients with this kind of intractable epilepsy can benefit from surgery.

Observation by ¹H MRS of two patients with a form of chronic localized epileptogenic encephalitis known as Rasmus-

sen's syndrome produced the first report of elevated lactate associated with seizure discharge in human brain.⁴⁶ Lactate elevation caused by seizure discharge is illustrated in Figure 1.

Monitoring of signals from γ -aminobutyric acid and glutamine in the human brain by newly developed ¹H MRS methods⁵⁰ has allowed direct observation of the effects of vigabatrin, a new antiepileptic drug.⁵¹ Such observation of drug effects directly in the living target organ opens a new era in neuropharmacology.

6 DEMENTIA

Primary dementia—decline of mental function not secondary to tumors, trauma, drugs, or other obvious causes—is about one-half dementia of the Alzheimer type (hereinafter 'Alzheimer disease'). Vascular, infectious, and other dementias are much less common. Alzheimer disease is a condition of unknown etiology that is defined by its characteristic neuropathology, although the diagnosis can usually be made correctly in life from its distinctive constellation of clinical and laboratory abnormalities. The protracted disability that it causes places a large burden on society, motivating intense research effort which now includes MRS.

6.1 ³¹P Studies of Alzheimer Disease

Published ³¹P data on Alzheimer patients do not agree with each other. Conflicting claims about what changes, if any, are present have persisted for several years. A series of studies recently summarized⁵² reported that PME and Pi were above normal in the brains of Alzheimer patients, while another group found no clear ³¹P changes associated with the disease.^{53,54} No obvious difference in patient selection or characterization accounts for the difference. Technical factors might; the two studies used somewhat different ³¹P acquisition methods.

6.2 ¹H Studies of Alzheimer Disease

In contrast to the ³¹P findings, ¹H MRS done by several groups has produced general agreement that a reduced NA signal is characteristic of Alzheimer disease (see Figure 1). Preliminary reports of nine studies of living Alzheimer patients all describe decreased NA signals (*Proc. 12th Ann Mtg. (Int) Soc. Magn. Reson. Med.*, New York, 1993). These very consistent data urge the conclusion that NA is characteristically reduced in Alzheimer disease, apparently in proportion to the severity of neuron loss.

7 BRAIN TUMORS

The cellular heterogeneity of brain tumors is a substantial impediment to progress in understanding neoplasia in the nervous system by in vivo techniques, as PET workers have known for years. The heterogeneity is far below the anatomical resolution of current MRS techniques, and technical improvements that appear feasible offer no hope that the gap can be closed. Its effects were evident in an early ³¹P MRS study of

brain tumors, which commented on the 'striking diversity' of the metabolic patterns observed.⁵⁵ Later studies associated decreased PCr, alkaline pH, increased PME, and altered PDE signals with heightened aggressivity of gliomas.^{56,57} One constellation of ³¹P changes that can occur in gliomas is illustrated in Figure 2.

More detailed observation of metabolic properties of brain tumors is possible by ¹H MRS due to its finer anatomical resolution. In the form of chemical shift imaging (CSI), it allows variations within single lesions to be detected. A study that combined ¹H CSI with PET found that regions of high lactate tended to coincide with regions of high glucose uptake.⁵⁸ Later work with improved techniques by the same group revealed a more complicated situation: high lactate was also associated with loculations of extracellular fluid.⁵⁹ Another group able to study patients with both ¹H CSI and PET reported similar variability and metabolic findings.^{60,61} Variable reductions in NA and increased choline signals were observed by both groups. These changes and the elevated lactate seen in some brain tumors are illustrated in Figure 1.

Metabolic maps made from ³¹P have lower anatomical resolution than ¹H maps, due to the lower sensitivity of ³¹P, but they are capable of showing metabolite distributions across major brain structures and defects caused by large lesions (also see the related *Chemical Shift Imaging*).^{62,63} The information about energy state, pH, and phospholipids available in ³¹P spectra is so valuable for the understanding of many disease states that continued vigorous efforts to refine ³¹P CSI are certain.

8 MULTIPLE SCLEROSIS

Demonstration of the extensive, clinically silent pathology of cerebral white matter in multiple sclerosis was among the first major new findings of MRI in the nervous system. MRS of the disease was not practical until several years later, for the usual reason that MRS signals are of much lower intensity. By 1993, NMR technology had advanced to the point that nine preliminary reports on ¹H MRS studies of multiple sclerosis appeared in that year's *Proc. 12th Ann Mtg. (Int) Soc. Magn. Reson. Med.* Reduced NA and increased choline signals associated with plaques were the most common findings. Elevated lactate was also observed; it may reflect the presence of highly glycolytic white cells, as in subacute cerebral infarction.¹⁶ All three changes are illustrated in Figure 1.

These metabolic abnormalities were followed over a period of months in a single multiple sclerosis patient with an unusually large cerebral plaque.⁶⁴ Metabolic aspects of plaque evolution have not previously been accessible for study in human patients. The combination of MRI and chemically specific MRS will produce new understanding of the pathophysiology of multiple sclerosis, as they are used together to obtain new information on the natural history and therapeutic responsiveness of the disease in individual patients. All of the data reported by Arnold and colleagues⁶⁴ are new information bearing on the underlying cellular and molecular biology of episodic demyelination. The opening of so wide a window on a pathophysiological process is certain to improve understanding of it.

9 THE FUTURE OF HUMAN BRAIN MRS

The chemical specificity of MRS guarantees a major role for it in neurobiology. That property, together with the noninvasiveness that it shares with all NMR methods, offers scope for the investigation of the normal human brain that has no close precedent in the history of any earlier technology. Detailed biochemical characterization of the living human brain at all its stages of development and decline is coming within the reach of noninvasive, chemically specific MRS. Investigation of how the human brain works when it is normal and when it is diseased will move more rapidly, and in new directions, with abundant benefit to both science and medicine.

9.1 Science

Neurochemistry is a difficult discipline, because nervous tissue is well protected and highly intolerant of the kind of disruption required for study by standard chemical techniques. MRS can reduce that barrier considerably by providing abundant neurochemical data from the living organ, free of agonal artifact and remeasurable as often as necessary in the same individual. The MRS studies of normal function and metabolic rates mentioned above are early examples of work that will grow into a new dimension of neurochemistry touching nearly every aspect of human brain biology. While MRS can measure only a small fraction of the compounds present in living brain, information about that fraction is unique because previously it was not available at all. Neurobiologists can now look through the window of several dozen MRS-measurable compounds at the biochemical milieu of which they are part. As the number of compounds observable in vivo grows, MRS will become an increasingly powerful complement to cellular and molecular methods in neurobiological research.

9.2 Medicine

In the late 1990s, no routine clinical application of MRS is yet standard practice of the kind that every hospital must provide, like X-ray equipment and electrocardiographs, but MRI has not reached that point either. Both will. Diagnostic MRI is so much more versatile and efficient than earlier technologies that its emergence as the premier medical imaging method of the latter 1990s is certain. Implementation of MRS (small signal capability) on standard clinical MRI machines is no longer a large step in either technique or money. The widespread availability of MRI machines needed for efficient medical diagnosis will facilitate the introduction of MRS into routine clinical practice as rapidly as MRS research demonstrates useful applications.

The most important prospect that MRS offers clinical medicine is chemically specific characterization of disease processes at all of their stages. Noninvasive longitudinal MRS data that provide new understanding of how pathophysiological processes evolve are unique. They will affect medicine no less than the data from microscopic and chemical study of removed brain tissue that are much of the basis for modern conceptions of disease. MRS-defined biochemical profiles that distinguish ischemic, neoplastic, inflammatory, degenerative, and other pathophysiological categories from each other in vivo will emerge, as will profiles that identify specific diseases. Many

MRS measurements will be useful in monitoring the effects of therapy. As this body of knowledge grows, the use of specific MRS measurements in the management of individual patients will become routine.

10 RECENT PROGRESS

This article was first written in 1994. In the four intervening years, MRS of the human brain has advanced rapidly, as have nearly all biomedical applications of NMR technology. Most of the advances in MRS have been along paths predictable from the work described in the article, which continues to provide useful orientation to the origins of a field that is both revolutionary and still young.

However, in several areas recent progress is either novel or extensive to a degree that the article does not adequately indicate. The following recent citations, which are mostly reviews, will help the interested reader find relevant literature.

10.1 Spectroscopic Imaging

This procedure, also known as chemical shift imaging, allows mapping of metabolites in two dimensions. The major technical problems that it presents have been the object of intense development efforts in recent years,^{65,66} and it has been used by several groups in clinical research studies on brain tumors,⁶⁷ multiple sclerosis,⁶⁸ and various aspects of brain metabolism.^{69,70}

10.2 High-field Magnets

Spectrometers suitable for human studies at fields as high as 4.1 T have been used in research for several years, and instruments with fields up to 8 T are under development. Notable examples of the neurobiologic opportunities opened by work at 4 T include improved observation of glucose⁷¹ and amino acid⁶⁹ resonances in the human brain.

10.3 Measurement of Brain pH in ¹H Spectra

Human ¹H MRS at 2.1 T has shown that a titrating signal from homocarnosine can provide a measure of cytosolic pH in neurons with high concentrations of that compound, probably a subset specialized for synaptic release of γ -aminobutyric acid.⁷² A general review of brain pH measurements by MRS has appeared.⁷³

1 INTRODUCTION

In recent years, it has been demonstrated that MRI is capable of detecting changes in cerebral blood volume,¹ flow,² and oxygenation,^{2–5} that accompany an increase in neuronal activity. MRI methods that observe these activation-induced changes have been termed functional MRI (fMRI).

The most widely used fMRI method for the noninvasive mapping of human brain activity is based on blood oxygenation level dependent (BOLD) contrast.⁶ A localized signal increase in activated cortical regions is generally observed using a time-course collection of T_2^* -weighted images. A working model of this phenomenon is that an increase in neuronal activity causes local vasodilatation, which in turn causes blood flow to increase in such a manner that the amount of paramagnetic deoxyhemoglobin in the local vasculature is reduced. This reduction causes an increase in spin coherence and, therefore, an increase in signal when using T_2 - or T_2^* -weighted pulse sequences.

Support for the hypothesized BOLD contrast mechanism, as it related to fMRI, comes from several studies. Local cerebral blood oxygenation has been observed to increase with neuronal activity.^{7–10} Brain tissue T_2 , T_2^* , and T_2' have been shown to be decreased and increased by cerebral blood oxygenation decreases and increases, respectively.^{6,11–15} In addition, brain activation has been shown to increase T_2 , T_2^* , and T_2' ,^{16–20} in proportions that show general agreement with mathematical simulations based on simplified models of the cerebral vasculature.^{21,22}

The applicability of fMRI depends on the degree to which the induced signal enhancement magnitude, location, and timing can be correlated with underlying neuronal activation. The signal enhancement magnitude is not only affected by MRI parameters, but is also dependent on hemodynamic factors (i.e. blood volume, oxygenation, vessel orientation, and radii), which vary significantly from voxel to voxel.

Correlation between BOLD signal enhancement magnitude and cerebral blood flow has, nevertheless, been observed. Visual cortex activation studies have shown that BOLD signal enhancement has essentially the same flicker frequency dependency² as that of cerebral blood flow changes observed using positron emission tomography (PET).²³

The fMRI signal enhancement location and distribution is also an issue. The upper limit of spatial resolution of fMRI may be influenced by the degree to which an activation induced modulation of the velocity or oxygenation of rapidly inflowing spins or large collecting veins may contribute to the signal change. Generally, the larger the collecting vessel, the more spatially removed the signal change is from the area of neuronal activation. Such vessel size weighting might depend strongly on the pulse sequence, field strength, and resolution used.^{16–26} Nevertheless, studies have shown that fMRI can reveal activity localized to patches of cortex smaller than 1.5 mm.²⁷

The temporal resolution of fMRI depends on the latency and consistency of the activation-induced signal change. Rise latency of 8–9 s from stimulus onset to maximal signal change and a fall latency of 9–10 s from stimulus cessation to baseline signal have been reported.^{2,28,29} The hemodynamic response time sets upper limits on the functional temporal resolution. A significant increase from baseline is generally observed to take place within 2–3 s after stimulus onset.^{2,28,29} Activation durations of less than 1 s are detectable^{30,31} and relative differences (in the rise time from adjacent regions or from different experiments) in the onset of signal enhancement are discriminable to within a second.³²

Platforms on which fMRI are performed vary considerably. Primary differences are in field strength, pulse sequence, gradient and radiofrequency coil hardware, and postprocessing methods. The many trade-offs that exist between platform types have not been completely characterized, but it is clear that fMRI based on BOLD contrast benefits from high field strength, high system stability, high signal-to-noise, (S/N) ratio, and minimal pulsatile motion sensitivity. From reported results, it appears that these criteria are most readily met using echo planar imaging. Nevertheless, other techniques may be suitable. Initial successes in the performance of fMRI using BOLD contrast were published by groups using either EPI at 1.5 T,^{2,3} and 4 T,¹⁶ or fast multishot gradient-recalled imaging techniques at 4 T,⁴ and at 2 T.⁵ Results have since been reported using fast multishot gradient-recalled imaging techniques at 1.5 T.^{33–35} Pulsatile brain, cerebrospinal fluid, and blood motion apparently cause nonrepeatable ghosting patterns in sequential images obtained by conventional multishot techniques,^{36,37} thus adding significantly to the image signal variation in time. Multishot spiral-scan techniques have lower sensitivity to these contaminating pulsatile effects,^{36,37} and have been used successfully to perform high resolution fMRI at 1.5 T.²⁷

The use of a time course of images in conjunction with control over activation timing allows for the application of postprocessing methods which include the use of z maps,³⁸ and other statistical techniques.³⁵ In addition, other methods, including Fourier analysis,³⁹ temporal cross correlation,³⁹ and time–frequency analysis⁴⁰ have been successfully applied. While significant signal changes are easily observed using the most conservative statistical tests, a standardized method by which functional images are created has not been established.

Using EPI, studies of the fluctuations in the susceptibility-weighted signal from a quiescent brain have been carried out,⁴¹ not only to determine the nature of the noise for application to statistical tests, but also to obtain potentially useful physiological information, and to determine the actual relationship between functional contrast to noise and field strength.⁴²

Because of the ease of use and accessibility of FMRI, many areas of the brain and many different tasks have already been studied. Studies that have been carried out include those of primary cortical regions including visual cortex,^{2, 4, 5, 16, 29, 35, 43} motor cortex,^{2, 3, 26, 33, 34, 39, 44–46} and auditory cortex.⁴⁷ Studies of higher cognitive function, including word generation,^{48, 49} higher visual processing,^{35, 43} visual recall,⁵⁰ complex motor control,⁴⁶ and single word semantic processing,⁵¹ have also been performed.

In this article, applications of FMRI to the mapping of cortex activated by sensory stimulation are summarized using time-course collection of gradient recalled echo planar images at 1.5 T,^{3, 39} and temporal crosscorrelation postprocessing techniques.³⁹ Specifically, auditory cortex regions were differentially activated by noise and speech sounds, and visual cortex regions were selectively activated by visual stimuli of different eccentricity.

2 POSTPROCESSING METHODOLOGY

Stimuli are presented in a repetitive on/off fashion for several cycles throughout each time course. Foci of brain activation are identified by crosscorrelation of the time course of each voxel with a reference vector resembling the expected activation-induced response.³⁹ In general, a reference vector may be obtained by: (a) choosing the voxel containing what appears to be the 'best' temporal response; (b) averaging, in time, the activation cycles in a 'best temporal response' voxel and then duplicating the time-averaged cycle for the length of the time course; (c) averaging in space several of the 'best temporal response' voxels; (d) synthesizing a reference vector; or (e) choosing a vector obtained from principal component analysis of the time course. Pixels having a temporal correlation coefficient below a given threshold (typically 0.4–0.6) are removed. After thresholding, the vector product of the reference vector with each of the surviving time courses is calculated to yield an index of change in the signal magnitude. These 'activation' images are then colorized and superimposed on high resolution anatomical scans of the same slice obtained in the same imaging session.

3 PULSE SEQUENCE AND HARDWARE

All studies presented in this article were performed using single-shot 64×64 gradient-recalled EPI ($TE = 40$ ms) on a clinical 1.5-T GE Signa scanner. To perform EPI without additional stress to the standard gradient amplifiers, we used an insertable balanced torque three-axis head gradient coil designed for rapid gradient switching.⁵² To obtain high-quality images throughout the entire brain volume, a shielded quadrature elliptical endcapped transmit/receive birdcage radiofrequency coil was used.⁵³ Typically, single-

or multi-slice time-course series of 64–1024 images were obtained with a TR of 0.5–3 s, flip angle of 65° – 90° , field of view (FOV) of 24 cm, and slice thickness of 4–10 mm.

4 AUDITORY STIMULI

This study⁴⁷ presents findings using FMRI of brain regions involved in auditory speech perception. Specifically, regions activated by speech sounds (words and pseudowords) and nonspeech sounds (noise) were compared.

Five right-handed subjects were tested. Symmetric lateral sagittal slices (slice thickness 10 mm) of the left and right hemispheres were obtained, centered at positions 8 mm medial to the most lateral point of the temporal lobe on each side. In each time-course series, 64 sequential images were collected ($TR = 3$ s), during which activation alternated with baseline every 9 s (6 images per cycle, 18 s per cycle, 10 cycles). During baseline periods, subjects heard only the ambient scanner noise. During activation periods, prepared digitized auditory stimuli were delivered to the subject via air conduction through a semi-rigid 1-cm-bore plastic tube. The tube conducted the sound stimulus approximately 20 feet from control room wall to the subject, at which point a Y-connector split the tube for binaural stimulation through a tightly fitting headset with occlusive earplugs to reduce scanner noise exposure.

Subjects passively listened to stimuli; no response was required. Stimuli differed in both semantic and acoustic (frequency modulation) content. White noise presentation was compared to presentation of nouns (e.g. 'barn'), and pseudowords (e.g. 'narb') with stimuli matched for duration, presentation rate, average sound pressure level, and spectral range. All voxels having a temporal correlation coefficient to a sinusoidal reference vector below 0.5 were removed. The activation images were superimposed on high resolution scans of the same slices.

Figure 1 illustrates typical results from two of the subjects studied with white noise, pseudowords, and words, respectively. In these and all other subjects studied, the area activated by white noise was considerably smaller than that activated by speech sounds, and was restricted to the dorsal aspect of the superior temporal gyrus. In most instances, this region coincided with or included the transverse temporal (Heschl's) gyrus. Presentation of speech sounds activated a larger region, including more anterior and posterior areas of the dorsal superior temporal gyrus, as well as cortex in or near the superior temporal sulcus bilaterally.

Both words and pseudowords differed significantly from noise bilaterally, while no significant differences were seen between word and pseudoword conditions. Activity occurred symmetrically in the left and right temporal lobes. Unlike white noise, therefore, processing of speech sounds appears to elicit extensive participation of auditory association areas, even when the subject is not engaged in any 'active' task.

5 VISUAL STIMULI

Much of the utility of FMRI depends on its ability to depict spatial patterns of neural activity. To test this capacity in the visual system, FMRI was used for retinotopic mapping of primary visual cortex activation.⁴³

Figure 1 Sagittal images of the left and right temporal lobes of two subjects. Demonstrated are regions activated during passive listening to (A) white noise, (B) pseudowords, and (C) words. The area activated by white noise was smaller than the area activated by either pseudowords or words. The area activated by pseudowords was generally the same size and shape as the area activated by words. Reproduced with permission of the American Neurological Association, 1994)

Dynamic, computer graphics-based visual images were directly projected onto the subjects' retinæ. The image generator was a modified Sharp XG2000U video projector driven by Cambridge Instruments VSG video graphics board installed in a personal computer. The image plane was then viewed through a custom optical system that included a wide field, magnifying eyepiece, a 45° prism, and additional objective lenses for adjusting magnification and minimizing chromatic aberration. Two sets of imaging optics were combined to provide full binocular viewing.⁵⁴

To map the retinotopic organization of the visual cortex, three highly trained subjects viewed a small white fixation dot on a uniform black or gray field subtending 60° of visual angle. A black-and-white checkered annulus surrounding the fixation point was presented for 5 on/off cycles of 10 s on and 10 s off. Time-course series ($TR = 2$ s) of 100 images (slice thickness 8 mm) were used. When on, the checkered pattern was either counter-phase modulated or flickered at 6–8 Hz. Six successively larger annuli were tested. The width of each annulus as well as the check size were scaled in proportion to eccentricity. Only voxels having a correlation coefficient above 0.55 with respect to a chosen reference vector were used in the creation of functional images. All functional images were then superimposed on high resolution anatomical scans.

Figure 2 illustrates the relative sizes of the annuli and shows the corresponding brain activation images. In these experiments, the subject passively viewed the stimuli and was not required to respond to them. A small checkerboard annulus presented at the fixation point elicited activation in striate cortex only at the occipital poles bilaterally. Annuli presented at increasing eccentricities activated successively more anterior

regions of the calcarine sulcus. The most eccentric stimulus activated only the anterior calcarine cortex while sparing the occipital poles. Detailed examination of the sequence of activity foci in Figure 2, shows a progression that closely follows the folded cortical mantle within the calcarine sulcus. While such a precise progression is not always observed, these data do show that, under optimal conditions, a detailed mapping of the visual field representation is possible with fMRI. Resolution is not limited by the coarseness of the distribution of large blood vessels, even though such vessels may sometimes introduce artifacts.

6 CONCLUSIONS

MRI of human brain activation using BOLD contrast is a relatively new functional brain imaging method. Accompanying the novelty of the technique are many unknowns regarding the upper limits of spatial and temporal resolution as well as an unclear understanding of physiological and the biophysical mechanisms that regulate hemodynamic changes. In addition, the ways in which the hemodynamic changes affect the magnetic resonance signal are incompletely understood. Nevertheless, the applications described here and elsewhere empirically establish the utility of this approach.

These studies demonstrate observation by fMRI of human brain activation by sensory stimulation. Regions activated in temporal lobes by various speech and nonspeech auditory stimuli were observed. In addition, retinotopic organization of the

Figure 2 Axial brain activation images created by passive viewing of visual stimuli with six different eccentricities while fixating at the center. The active foci traveled in an anterior direction along the calcarine fissure as the stimulus became more peripheral

primary visual cortex was observed using stimuli of varying visual field eccentricity. Additionally, in our laboratory, preliminary studies involving activation by tactile, aromatic, and taste stimuli are in progress.

fMRI is a new technique that holds great promise in uncovering unique and useful information about brain function and physiology.

Peter A. Bandettini. b 1966. B.S., 1989, Ph.D., 1994, Biophysics, Medical College of Wisconsin, USA (supervisors James S. Hyde and R. Scott Hinks). Postdoctoral fellow, Massachusetts General Hospital NMR Center, 1994–95. Approx. 15 publications. Research specialties: functional MRI contrast mechanisms, postprocessing techniques, and applications.

Jeffrey R. Binder. b 1958. B.M., 1980, M.D., 1986, University of Nebraska, USA. Neurology Residency, 1987–90. Neurological Institute of New York. Fellow in cerebrovascular disease, 1990–92. Neurological Institute (with J. P. Mohr). Currently Assistant Professor of Neurology, Medical College of Wisconsin, USA. Approx. 15 publications. Research specialties: behavioral neurology, neuroscience applications of functional MRI, cerebrovascular disease.

Edgar A. DeYoe III. b 1950. B.S. Electrical Engineering, 1972; Ph.D. 1983, Experimental Psychology; Ph.D. 1983, Neuroscience, University of Rochester, USA (Advisor: Robert W. Doty). Postdoctoral fellowship at California Institute of Technology (Supervisor: David Van Essen). Currently assistant professor in Department of Cellular Biology and Anatomy with adjunct appointment to Department of Biophysics at the Medical College of Wisconsin, Milwaukee, WI. Approx. 21 publications. Research interests: Neural mechanisms of visual perception—anatomy and physiology; Functional magnetic resonance imaging (fMRI) of the human visual system; development of systems for testing normal vision and visual system; development of systems for testing normal vision and visual dysfunction during fMRI.

James S. Hyde. b 1932. B.S., 1954, Ph.D., 1959, Physics, M.I.T., Cambridge, MA, USA. Member of the scientific staff, Varian Associates, 1959–75, working under the direction of W. A. Anderson and M. E. Packard. Professor of Biophysics, Medical College of Wisconsin, 1975–present. Approx. 275 publications, 27 patents. Research specialties: ESR spectroscopy, ENDOR, musculoskeletal MRI, surface coils, functional MRI, electron and nuclear spin physics, and magnetic resonance instrumentation.

Fluorine-19 MRS: General Overview and Anesthesia

David K. Menon

University of Cambridge, UK

1 INTRODUCTION

Fluorine-19 has 100% natural abundance and possesses a spin of $\frac{1}{2}$ and an NMR sensitivity of 80–85% relative to protons. Consequently, fluorine-containing compounds produce NMR signals that are nearly as easily detected as proton signals. The range of chemical shifts for ^{19}F compounds is about 1000 ppm, far greater than that observed for ^1H spectroscopy, leading to much greater spectral dispersion. These attributes, coupled with the fact that ^{19}F magnetic resonance (MR) does not require solvent suppression, would be expected to make it an ideal nucleus for study in biological systems. Unfortunately, no naturally occurring molecules of biological consequence contain adequate concentrations of MR-visible ^{19}F (bone and teeth contain a substantial amount of ^{19}F , but this is contained in compounds that possess extremely short T_2 values). However, several pharmacologically active compounds contain fluorine, and ^{19}F magnetic resonance spectroscopy (MRS) has been used for the study of the biodistribution, pharmacokinetics, and metabolism of several drugs.¹ Other groups have also used ^{19}F -containing compounds as tracers for blood,² either to image tissue blood flow (perfusion) or intravascular volume (angiography). In addition, ^{19}F chemical shifts and relaxation parameters can be greatly influenced by the physical and chemical environment, and ^{19}F containing molecules in biological systems exhibit significant and variable $^{19}\text{F}\{^1\text{H}\}$ nuclear Overhauser effects (NOEs) which depend on their chemical environment and mobility.³ These properties allow ^{19}F MR to be used to probe molecular interactions in biological systems.

Section 2 of this article provides an overview of the applications of in vivo ^{19}F MR to biological systems, while Section 3 covers the application of ^{19}F MR to research in anesthesia.

2 APPLICATIONS OF ^{19}F MR: AN OVERVIEW

In the following discussion illustrative examples are described, the aim being to outline the principles of applications of ^{19}F MR. The discussion will focus on experiments that have involved whole body in vivo MR either in experimental animals or in humans, but occasional reference will be made to in vitro studies of tissue preparations or cell cultures to illustrate a potential in vivo application.

2.1 Biodistribution and Pharmacokinetics

^{19}F MRS has been used to study the biodistribution of volatile anesthetic agents and antimitotic compounds, and studies

addressing this area are discussed in some detail in later sections of this article. In addition, the technique has also been used to study the metabolism of other drugs, two examples of which are discussed here.

Karson et al.⁴ studied subjects being treated with the anti-depressant agent fluoxetine, and found brain concentrations of $1.3\text{--}5.7\ \mu\text{g mL}^{-1}$ on a daily dose of $40\ \text{mg day}^{-1}$ in volunteers. They found acquisition of signals from patients more difficult, but suggested a correlation between dose and measured brain concentrations. In a more recent paper,⁵ the same group describe the use of a quadrature coil for localized ^{19}F MRS of fluoxetine in patients and reported on T_1 and T_2 values for the fluoxetine resonance, which was predominantly intracerebral in location. Ex vivo ^{19}F MRS of brain obtained from patients at autopsy showed that at least part of the in vivo resonance was due to the active metabolite norfluoxetine, and in vitro analysis of lipid extracts of brain showed far higher concentrations ($12.3\text{--}18.6\ \mu\text{g mL}^{-1}$) than were observed in vivo, suggesting that some of the compound may be NMR invisible in vivo. These studies clearly demonstrate that, while ^{19}F MRS is technically suitable for clinical pharmacokinetic research, in vivo MRS needs to be underpinned in its initial phases by ex vivo and in vitro data. Relevant clinical studies might investigate the relationship of brain concentrations to drug response, and the behavior of brain concentrations in relation to changes in dosage schedules.

Lee et al.⁶ used ^{19}F MRS to study the rate of absorption of the nonsteroidal antiinflammatory agent flubiprofen from a topical preparation in an animal model. This technique may be easily transferred to human studies, and may provide substantial advantages over traditional methods (which either involve excised human skin or require the use of radioisotope labeling) for studying transcutaneous drug absorption.

2.2 Metabolism

Most work reported in the literature has concentrated on the metabolism of drugs, and several examples are discussed in later sections in the context of volatile anesthetic agents and antimitotics. However, ^{19}F MRS may also be used to study the metabolism of modified physiological substrate molecules.

Some recent studies have investigated the use of fluorinated glucose analogs, such as 2-fluoro-2-deoxy-D-glucose (2-FDG), in imaging glucose utilization in intact animals.^{7–9} Such studies provide a regional map of glucose utilization in a manner analogous to ^{18}F FDG positron emission tomography (PET), but without the need to expose subjects to radiation.⁷ In addition, ^{19}F MRS also provides the ability to interrogate individual metabolic pathways by detecting and quantifying downstream metabolites. Thus, 3-fluoro-3-deoxy-D-glucose (3-FDG) has been used to study glucose metabolism to sorbitol via the aldose reductase pathway,⁹ a process that is thought to be intimately involved in the pathogenesis of diabetic cataract and peripheral neuropathy. This is of particular relevance because of the need to evaluate new aldose reductase inhibitors which may be of use in postponing or avoiding the long-term complications of diabetes mellitus. Unfortunately, while many animal studies are underway, the large doses of FDG required, coupled with the potential toxicity of the molecule, dictate that clinical studies are not likely to be possible in the immediate future.

2.3 Insights into Molecular Mechanisms of Drug Action and Metabolism

The interaction of ^{19}F -containing compounds with other molecules at their site of action may be elucidated by studying changes in NMR properties, including T_1 , T_2 , and NOE values. Such information may provide insight into the mechanisms of action or metabolism of drugs. For example, the demonstration of short T_2 environments for volatile anesthetics in the brain in some studies implies that the agents may be immobilized at their site of residence (see later), and that this environment is substantially different from that in adipose tissue, where these agents possess long T_2 values. This distinction may be of considerable importance in validating putative mechanisms of action of volatile anesthetic agents.

The T_1 relaxation of fluorinated compounds in biological systems is dominated by ^1H - ^{19}F interactions,¹⁰ and the resulting NOEs can provide useful information regarding these interactions.³ In small molecules, irradiation of the proton frequency often results in an enhancement of signal intensity (a positive NOE). In other systems, where the ^{19}F nucleus is bound to a large molecule (e.g. a protein), the NOE is typically negative (i.e. there is a reduction in signal intensity with irradiation of the proton frequency). In situations where the ^{19}F nucleus under study is part of a small molecule which attaches reversibly to a macromolecule, the observed NOE depends on the mole fraction of the small molecule that is bound and its rate of dissociation from the complex. In many biological systems the observed effects are dominated by macromolecular binding, even when the bound fraction is small and the rate of dissociation slow. Jacobson et al.³ have used these effects to investigate the interaction of a cytochrome P450 inducer and a novel herbicide with macromolecules in the liver using in vivo ^{19}F MRS, and the technique may be applicable to many more experimental situations. Direct transfer to human research must be preceded by studies that estimate energy deposition produced by ^1H irradiation, but this is unlikely to be major problem, since similar issues have been addressed in the context of ^{13}C and ^{31}P MRS.

2.4 Information Regarding Physicochemical Environment

The T_1 of perfluorocarbons varies with, and may thus provide information regarding, their chemical and physical environment. The paramagnetic O_2 molecule reduces their T_1 from 1–4 to 0.3–0.5 s in linear proportion to the local partial pressure of oxygen.¹¹ When administered intravenously, these compounds are sequestered in tissues, where their T_1 value provides a measure of $p\text{O}_2$. Alternatively, the compound may be directly introduced into the site of interest (e.g. the vitreous humor). This technique has been used to estimate tissue $p\text{O}_2$ in experimental tumors, vitreous humor in animals and humans, and in animal myocardium.

Unfortunately, the T_1 of fluorocarbons also varies with temperature, making estimation of $p\text{O}_2$ difficult in experimental situations such as brain ischemia where there may be simultaneous changes in temperature. Berkowitz et al.¹² suggest the use of the compound perfluorotributylamine (FTBA) in this situation. While the T_1 value of FTBA changes with $p\text{O}_2$ and temperature, the chemical shift of its ^{19}F resonance is indepen-

dent of $p\text{O}_2$, but shows a linear change with temperature. ^{19}F MRS of this compound can thus provide an independent measure of the tissue temperature from chemical shift data, and the resulting information can be used to correct T_1 data to provide independent and valid measures of $p\text{O}_2$.

The chemical shift of other ^{19}F compounds is sensitive to pH, and ^{19}F MRS has been used to measure pH in biological systems. For example, Beech and Iles¹³ used the chemical shift of exogenously administered F-Quene 1 to estimate intracellular pH (pH_i) in rat liver in vivo. While the technique was practicable, it did not work consistently, and they found small differences when comparisons were made to estimates of pH_i from ^{31}P MRS (using the chemical shift of P_i).

Finally, when ^{19}F is covalently attached to various chelators (e.g. 5,5'-difluoro-1,2-bis(*o*-aminophenoxy)ethane-*N,N,N',N'*-tetraacetic acid (5-FBAPTA)), the ^{19}F chemical shift of the resultant compound is sensitive to binding by cations, and the local concentration of many cations (of which calcium is the most biologically important) can be estimated by measuring the relative concentration of the bound species. 5-FBAPTA and other fluorinated chelates have been used to study intracellular Ca^{2+} concentrations in cell preparations and tissue slices,¹⁴ and more recent studies have used the techniques to quantify other cations.¹⁵ However, no in vivo study has been reported.

2.5 Imaging of Large Vessel Flow and Tissue Perfusion

The perfluorocarbons have been used as 'contrast agents' for ^{19}F angiography, with varying degrees of success.^{2,16} While their distribution in tissues provides a measure of local tissue blood flow, they do not give a true estimate of perfusion since they are retained in the intravascular compartment, and are not freely diffusible tracers. However, ^{19}F -containing gases and vapors are freely diffusible and can be used as tracers for estimating brain perfusion. Rudin and Sauter¹⁷ used the washout of halothane to estimate cerebral blood flow (CBF) in rats. However, halothane is known to be a potent cerebral vasodilator and increases CBF in the doses used in this study. Consequently, its use to determine CBF is inappropriate. However, Pekar et al.¹⁸ administered the inert diffusible gas trifluoromethane via the inhalational route in cats, and estimated CBF from wash-in and wash-out data. Their results suggest that the measurement of rCBF may be possible using this technique, with a spatial resolution of 0.4 mL, at least in experimental animals.

3 ^{19}F MRS STUDIES OF FLUORINATED ANESTHETIC AGENTS

3.1 Clinical and Pharmacological Context

Recent ^{19}F MRS studies of fluorinated anesthetics have been the source of some controversy, as results from some groups challenge generally held notions of anesthetic action. Two main issues are pertinent: (a) theories regarding the site of action of anesthetic agents; and (b) the duration of residence of modern anesthetic agents in the brain. Conventional viewpoints on these issues are briefly described below, in order to put the following discussion into some sort of context.

Figure 1 Chemical structures of general anesthetic agents in common clinical use

General anesthetic agents vary widely in chemical structure (Figure 1), but still continue to have surprisingly similar behavioral effects. However, we have little information on how and where they act in the brain. Two opposing theories claim very different sites of anesthetic action.¹⁹ One school of thought attributes general anesthesia to action at a nonspecific hydrophobic site in the lipid bilayer of cell membranes which is 'disordered' by the entry of the anesthetic molecule.²⁰ The opposing school of thought suggests that these agents may act at specific stereoselective hydrophilic sites on membrane proteins.²¹ Data that suggest molecular specificity of the interaction between anesthetic agents and the brain would provide support to the second theory.²¹

The fluorinated volatile agents constitute the most widely used class of general anesthetics in the world, and individual agents that are presently in use (Figure 1) include halothane, enflurane, isoflurane, sevoflurane, and desflurane.²² These compounds are characterized, on clinical grounds, by an apparently rapid onset and offset of action. Conventionally, the rapidity of wash-in and wash-out of an anesthetic agent is thought to vary inversely with its solubility in blood and tissue.²² On this basis, the agents mentioned above rank as follows: desflurane > sevoflurane > isoflurane > enflurane > halothane, where halothane has the highest blood gas solubility, and hence slowest wash-in and wash-out characteristics²² (Figure 2). Nevertheless, even with halothane, the offset of clinical anesthesia is relatively rapid, with patients awakening within a few minutes of ceasing administration of the agent. However, patients are reported to continue to have subtle psychomotor impairments for several hours to days after general anesthesia.²³

3.2 Pharmacokinetics of Fluorinated Anesthetics: Is Anesthetic Residence Prolonged in the Brain?

Over the last 10 years there have been numerous papers from several groups that have used ^{19}F MRS to study anesthetic action in the brain. These address two main issues; the first of which is discussed in this section; the second issue is discussed in Section 3.3.

The first in vivo surface coil study of fluorinated anesthetics demonstrated the feasibility of such studies, and suggested that

Figure 2 Increase in the alveolar fractional concentration (F_{A_x}) toward that of inspired fractional concentration (F_{I_x}) with time, compared for different fluorinated volatile agents. Note that the less soluble agents (isoflurane and desflurane) show a more rapid rise

the compounds could be detected in the brain for substantially longer than had been expected.²⁴ Further studies from Wyrwicz et al.²⁵ conducted with 2.8 cm surface coil on the scalp, suggested that, following a 2-h exposure to 1% halothane, halothane was washed out of rabbit brain with a biexponential temporal profile (Figure 3). The initial rapid decay had a time constant of approximately 25 min, while the later slower wash-out phase had a time constant of 320 min. These findings were confirmed by in vitro ^{19}F MRS of extracts of excised rabbit brain at different intervals after the cessation of anesthesia (Figure 4). Although figures for washout half-times were not presented for the in vitro data, they were reported to show an 'elimination profile similar to that observed in intact animals'. These in vitro studies provided better spectral resolution than in vivo studies, and showed that, starting at 90 min after cessation of halothane anesthesia, brain halothane could be resolved into two resonances: a doublet with a 5.6 Hz proton J coupling that was attributed to the trifluoromethyl resonance of halothane, and a second peak 0.7 ppm downfield whose proportion increased with time, such that it represented 40% of the residual ^{19}F signal by 6 h. These two resonances were also differentiated by their relaxation properties. The halothane resonance showed a T_1 of 1.3 s and a T_2 of 3.8 ms, while the new singlet resonance had a T_1 of 2.8 s and a T_2 of 10.6 ms, suggesting that the two resonances were in different chemical environments. Further subcellular fractionation showed that the singlet resonance was confined to the cytosol, while the halothane trifluoromethyl resonance was widely present, and was loosely bound, being dissociated from cellular components by washing with 0.32 M sucrose. The authors concluded that the new singlet resonance represented a nonvolatile metabolite of halothane, possibly trifluoroacetate.

These findings were surprising, since they implied prolonged halothane residence in the brain, a concept that flew in the face of conventional perfusion-limited models of anesthetic elimination.²⁶ The possibility that a nonvolatile metabolite might be responsible for the prolonged ^{19}F signal provides some explanation for these findings, but did not account for the fact that even 6 h after anesthesia, 60% of the observed ^{19}F signal in excised brain appeared to arise from the trifluoro-

Figure 3 A representative time course of decay of the ^{19}F signal from halothane during recovery from anesthesia. Spectra were obtained during a pulse-and-collect experiment with a surface coil placed over the head of a rabbit after a 120-min exposure to 1% halothane. All signal intensities are expressed as a percentage of the initial signal obtained. (Reproduced with permission from A. M. Wyrwicz, C. B. Conboy, B. G. Nichols, K. R. Ryback, and P. Eisle, *Biochim. Biophys. Acta*, 1987, **929**, 271)

methyl resonance of unmetabolized halothane.²⁵ Furthermore, this theory could not explain the fact that in a similar experiment Wyrwicz et al.²⁷ observed similar two-compartment elimination for isoflurane (Figure 5), a compound that is only minimally (<1%) metabolized.²⁸ The initial decay phase for both halothane and isoflurane were similar ($t_{1/2}$ of 25 and 26 min, respectively), but the later elimination of halothane was significantly slower than isoflurane ($t_{1/2}$ of 320 and 174 min, respectively). The authors suggested that the slow, late elimination of halothane could be attributed to its greater tissue solubility and the presence of nonvolatile metabolites.

While the two pharmacokinetic compartments might represent brain tissue with varying perfusion (e.g. gray and white matter), the $t_{1/2}$ values were at odds with data obtained from non-NMR techniques. Cohen et al.²⁹ administered labeled halothane intravenously, and found minimal (<10%) retention of radiolabel after 20 min. Similarly, Wolff³⁰ found that 97% of a subanesthetic dose of halothane was eliminated within 3 h. However, it has been argued by Topham and Longshaw³¹ that the pharmacokinetics of halothane may be significantly dependent on the route of administration and the dose administered. Consequently, the preceding two experiments may be irrelevant to the process of clinical anesthesia. Indeed, Divakaran et al.³² used gas chromatography to measure halothane levels in excised brain, and found elimination rates that correlate well with the figures obtained by Wyrwicz et al. However, Strum et al.³³ used gas chromatography to measure residual concentrations of isoflurane in rabbit tissue following 90 min of 1.3% isoflurane administration, and showed that brain concentrations of isoflurane were reduced to about 10% by 90 min.

In an effort to address these discrepancies, the research group at the University of California studied elimination of halothane and isoflurane in animal models. They hypothesized that much of the delayed elimination in published *in vivo* studies arose from contaminating signals in extracranial tissue,

where volatile anesthetics tend to be retained, owing to lower perfusion. Accordingly, they used a spatially selective depth pulse in an effort to obtain a selective signal from deeper brain tissue during ^{19}F MRS studies of halothane elimination in rats.³⁴ They found that the ^{19}F NMR signal from halothane decreased to 40% of its initial value by 34 min (in contrast to about 240 min as reported by Wyrwicz et al.²⁵). Several factors may have explained this discrepancy. First, halothane elimination may be significantly faster in rats when compared with rabbits. Second, the depth pulse imposed an acquisition delay of about 0.5 ms, and may have resulted in significant loss of signal from the short T_2 component. In a separate paper,³⁵ the same group reported data on isoflurane elimination in rabbits with two protocols, both obtained with pulse-and-collect sequences (Figure 6). In the first set of experiments they used

Figure 4 High-resolution ^{19}F MRS experiments on excised rabbit brain removed after varying periods of recovery (between 0 and 6 h) following halothane anesthesia. Chemical shifts are reported relative to an external 5 mM trifluoroacetic acid standard. Note the appearance of a new resonance in the 90-min spectrum, attributed to trifluoroacetic acid. Figure 5 A representative time course of decay of the ^{19}F signal from isoflurane during recovery from anesthesia. Spectra were obtained during a pulse-and-collect experiment with a surface coil placed over the head of a rabbit after a 90-min exposure to 1.5% isoflurane. All signal intensities are expressed as a percentage of the initial signal obtained. (Reproduced with permission from A. M. Wyrwicz, C. B. Conboy, K. R. Ryback, B. G. Nichols, and P. Eisele, *Biochim. Biophys. Acta*, 1987, **927**, 86)

a 3 cm surface coil over the scalp, similar to that employed by Wyrwicz et al.,²⁷ and found similar kinetics for isoflurane elimination. In another experiment they placed a 1 cm surface coil directly over the exposed dura in rabbits. This study revealed a monoexponential decay of isoflurane concentrations in the brain, with a reduction to 15% of initial values by 90 min. These data agreed well with findings of Strum et al.,³³ who used non-NMR methods and showed a reduction to 10% of initial values by 90 min. The University of California group concluded that the later prolonged elimination kinetics for iso-

Figure 6 Time course of decay of the ^{19}F signal from isoflurane during recovery from anesthesia. Spectra were obtained during a pulse-and-collect experiment with a surface coil placed over the head of a rabbit after a 90-min exposure to 1.5% isoflurane. All signal intensities are expressed, on a log scale, as a percentage of the initial signal obtained. (○) Signal obtained from a 1.0 cm diameter surface coil placed directly over the dura in craniectomized animals, fitted to a single exponential decay. (●) Signal obtained from a similar experiment, acquired using a 3.0 cm diameter surface coil placed over the intact scalp of the rabbit; the line represents the optimum least-squares fit for a biexponential decay. flurane observed by Wyrwicz et al. arose from signal contamination by isoflurane in extracerebral tissues.

The papers discussed above show that the issue of the spatial localization of the ^{19}F signal from anesthetic agents is an important one. Attempts have been made to clarify this point using ^{19}F MRI studies. While both spin echo³⁶ and gradient echo³⁷ sequences have been used to image halothane and enflurane in anesthetized animals, the echo times for these imaging studies have been 9 and 10 ms, respectively. As the T_2 of volatile anesthetics in the brain is short (typically 3–4 ms),²⁵ it is not surprising that these studies were unable to demonstrate any anesthetic in the brain, despite being conducted while the animal was still anesthetized. On the other hand, they clearly demonstrate fairly high concentrations of fluorinated agent in extracerebral tissues. When these distributions were compared with either ^1H lipid imaging³⁶ or ^{13}C imaging,³⁷ it appeared that the anesthetics localized in lipid rich areas in adipose tissue stores, glands, and muscle. Localized spectroscopy of volatile anesthetic agents therefore demands techniques that do not involve appreciable delays in data acquisition.

Wyrwicz and Conboy³⁸ used rotating frame zeumatography (RFZ) to examine the distribution of halothane in the rat head. Localized spectra were obtained from animals that were allowed to recover for varying periods after 90 min of anesthesia with 1% halothane (Figure 7). The localization of signals was necessarily imperfect since RFZ localizes signals along a single axis only. However, the ^{19}F spectra obtained immediately after anesthesia demonstrated very little variation in chemical shift across most of the rat head, but a heterogeneous distribution of ^{19}F signal across the animal's head with apparently lower peak heights in the 'brain' slices [Figures 7(a) and (b)]. The authors did not report on variations in T_2 or line-widths across the blocks of spectra, so estimates of signal intensity are impossible to obtain. RFZ experiments after 4.5 and 6.5 h of recovery from anesthesia showed signals from both halothane and halothane metabolite in all areas of the head [Figures 7(c) and (d)]. With time, the proportion of ^{19}F signal arising from halothane decreased, but this reduction followed a heterogeneous pattern across the head with more rapid reductions being seen in the 'brain' slices. Nevertheless, spectra obtained at 6.5 h (390 min) continued to show clearly detectable peaks from halothane in 'brain' slices. As the metabolite signal contribution increased, its distribution also changed, with a larger proportion of the ^{19}F signal arising from the brain. By 10 h after anesthesia, virtually all the ^{19}F signal arose from the metabolite resonance, and was mainly confined to 'brain' slices. No information regarding relative changes in signal intensity over time in different regions was provided, so even crude estimates of regional elimination half-lives are impossible.

In a more recent study, Lockhart et al.³⁹ measured the cerebral uptake and elimination of halothane, isoflurane, and desflurane from rabbit brain, using a 1 cm surface coil positioned over the exposed dura. They found that rates of change of cerebral concentrations of anesthetic paralleled alveolar levels, and both cerebral uptake and elimination of desflurane were 3 times as fast as for halothane and 1.7 times as fast as for isoflurane (Figure 8). These findings would fit with standard clinical and pharmacokinetic premises, since desflurane has a rapid onset and offset of action owing to its lower blood and tissue solubility. The data for the elimination of isoflurane were similar to those

obtained from the previous University of California study, with a monoexponential decay and only 10% of initial levels retained in the brain 90 min after discontinuation of isoflurane. The data also clearly demonstrate a hysteresis between alveolar and cerebral levels of all three volatile agents; alveolar concentrations were higher during the uptake phase, while cerebral concentrations were higher during the elimination phase (Figure 9). This is consistent with conventional pharmacokinetic modeling. However, it was found that the degree of hysteresis was identical for all three agents, suggesting that the rates of transfer between brain and blood are governed by factors other than blood and tissue solubility.

Chen et al.⁴⁰ studied elimination of isoflurane from the rat brain as a function of age using ^{19}F MRS with a surface coil. They found a biphasic elimination of isoflurane in both age groups with $t_{1/2}$ values of 7–9 and 100–115 min for the fast and slow components, respectively. The $t_{1/2}$ estimates for the fast compartment are consistent with data for elimination of isoflurane from the brain obtained using other techniques. Consequently, the authors attributed the slow component to wash-out of isoflurane from intracranial fatty tissue. They also found that older rats showed a slower elimination of isoflurane than younger rats, a difference that the authors attributed to impaired cardiovascular function.

What inferences can we draw from this review of ^{19}F MRS studies of the cerebral pharmacokinetics of anesthetic agents? Clearly, ^{19}F MRS provides a convenient technique for investigating these questions, but several issues need to be addressed. These include efficient spatial localization without acquisition delays, which will result in the loss of signal from short T_2 components. While many of the studies that reported prolonged anesthetic residence in the brain may have been flawed due to contamination by signal from extracerebral tissues, three points cannot be ignored. First, many MR studies tend to suggest slower anesthetic elimination from the brain when compared to non-NMR techniques. However, two more recent studies^{39,40} suggest brain isoflurane kinetics that are similar to those obtained from non-NMR techniques. Second, the RFZ studies strongly suggest the presence of residual unmetabolized anesthetic in the brain as long as 6.5 h after anesthesia.³⁸ Finally, prolonged residence of at least some proportion of halothane is supported by the in vitro studies of brain extracts per-

Figure 7 Results of localized ^{19}F MRS using rotating frame zeumatography performed following administration of 1.5% halothane for 90 min. (a) One-dimensional projection across the rabbit head (from above downwards) showing the location of different blocks of spectra: 1, soft tissue (skin and muscle); 2, brain, muscle, and calvarium; 3, brain; 4, brain, muscle, and calvarium; 5, tissue below the cranium. (b) Stacked, spatially resolved spectra obtained immediately after discontinuing anesthesia, blocks are numbered as in (a). (c) Stacked, spatially resolved spectra obtained 4.5 h after cessation of anesthesia. Note the appearance of a new resonance to the left of the halothane resonance, which is attributed to trifluoroacetic acid. (d) Stacked, spatially resolved spectra obtained 6.5 h after cessation of anesthesia. Note the decrease in intensity of the halothane resonance, and the increase in the intensity of the metabolite resonance. (Reproduced with permission from A. M. Wyrwicz and C. B. Conboy, *Magn. Reson. Med.*, 1989, **9**, 219)

formed by Wyrwicz et al.²⁵ However, as several of the later studies have shown, this may be an extremely small proportion of the initial concentrations.

These small quantities of residual cerebral anesthetic are important for two reasons. First, they may provide an explanation for the minor but prolonged psychomotor deficits that are recognized to persist for up to days after general anesthesia.²³ Second, elucidation of the mechanisms that result in prolonged anesthetic retention may provide clues regarding the mechanisms of anesthetic action.

3.3 Sites of Anesthetic Residence in the Brain: Physical Environment and its Significance, Saturability

Many authors have reported that volatile anesthetics in the brain exhibit shorter T_2 values than when they are dissolved in lipid solvents or adipose tissue. These findings have been interpreted as implying immobilization of the fluorinated anesthetic molecules, and have led to speculation that the short T_2 en-

Figure 9 Plot of the relationship between cerebral and alveolar concentrations of volatile anesthetics during induction of and recovery from anesthesia (lower and upper halves of ellipsoid, respectively). Both parts of the curve deviate from the line of identity (straight line), suggesting a significant hysteresis between alveolar and brain levels of anesthesia. Note the unexpected result showing that all three anesthetic agents studied seem to fit to the same curve. (Reproduced with permission from S. H. Lockhart, Y. Cohen, N. Yasuda, B. Freire, S. Taheri, L. Litt, and E. I. Eger II, *Anesthesiology*, 1991, **74**, 575)

vironment may be intimately related to the process of anesthesia. These latter speculations were further fuelled by the results of a study by Evers et al.⁴¹ in which T_2 values of four fluorinated anesthetic agents (methoxyflurane, enflurane, isoflurane, and fluoroxene) and one nonanesthetic fluorinated hydrocarbon (hexafluoroethane) in the brain were compared. The T_2 values of the four anesthetic agents were significantly shorter than in adipose tissue (0.5–4.5 versus 200–400 ms, respectively) and correlated linearly with the anesthetic potency of these agents (Figure 10). The nonanesthetic fluorocarbon exhibited a substantially higher T_2 (18.5 ms) in brain tissue.

Figure 10 Relationship of anesthetic potency (measured as ED₅₀) to ^{19}F spin-spin relaxation times of fluorinated volatile anesthetics in the brain. (Reproduced with permission from A. S. Evers, J. C. Haycock, and D. A. d'Avignon, *Biochem. Biophys. Res. Commun.*, 1988, **151**, 1039)

Figure 11 Brain halothane concentrations in rats as a function of inspired halothane concentrations, measured using either in vivo ^{19}F MRS ($\circ$) or ex vivo ^{19}F MRS ($\bullet$) of excised brain. The horizontal dashed line indicates the half-maximal concentration of brain halothane concentration achieved in this experiment. This value (about 1.2%) corresponds closely to the ED_{50} for halothane in rats. The inset shows a representative ^{19}F MR spectrum from the ex vivo experiments. The resonance at 0 ppm arises from methoxyflurane in an external standard, while the peak at 10.2 ppm corresponds to halothane in the brain. (Reproduced with permission from A. S. Evers, B. A. Berkowitz, and D. A. d'Avignon, *Nature*, 1987, **328**, 157)

These data were interpreted as supporting the premise that the short T_2 environment represented a molecular site of anesthetic action.

In a later study, Evers et al.^{42a} studied spontaneously breathing rats, anesthetized with halothane, using high resolution in vitro ^{19}F MRS of excised brain at different anesthetic concentrations and in vivo MRS of whole animals at 4.7 T. These experiments showed increasing cerebral levels of anesthetic with increasing inspired concentrations of halothane up to 2.5%. However, little or no further increases in cerebral halothane concentrations were observed when inspired halothane concentrations were increased from 2.5% to 4% (Figure 11). These data were interpreted as evidence for abundant saturable binding sites for halothane, a concept that did not support a nonspecific hydrophobic site of action of volatile anesthetic agents. Evers et al. also measured the T_2 relaxation parameters for the brain halothane resonance, and found that there were at least two components, with one T_2 value of about 3.6 ms (short T_2) and a second one of about 43 ms (long T_2). They also showed that the short T_2 site represented 85% of the halothane molecules present in the brain, and was preferentially occupied during the initial period of induction of anesthesia (Figure 12). Continuing anesthetic administration beyond this point seemed to occupy the long T_2 site. These findings were thought to provide further proof for the importance of the short T_2 site in the process of anesthesia. Unfortunately, these conclusions had to be revised owing to further experimental results.

Figure 12 Decay of the ^{19}F MR signal from brain halothane in rats as a function of echo time (expressed as τ) in a Carr-Purcell-Meiboom-Gill sequence from rats exposed to 3% halothane for 2 min ($\circ$) or 1 h ($\bullet$). Note the biexponential T_2 decay of the signal from rats exposed to halothane for 1 h, and the minimal increase in the amount of signal with short T_2 characteristics with longer exposure. (Reproduced with permission from A. S. Evers, B. A. Berkowitz, and D. A. d'Avignon, *Nature*, 1987, **328**, 157)

First, both Evers et al.^{42b} and Litt et al.⁴³ reported that the apparent saturability of brain halothane concentrations was a physiological artifact, being the consequence of respiratory depression at high inspired concentrations of halothane in spontaneously breathing animals. When the studies were repeated with artificially ventilated animals, the cerebral anesthetic concentrations scaled linearly with inspired concentrations of halothane (Figure 13). Furthermore, the short T_2 environment was not specific to brain,⁴⁴ but was also found in other tissues, including red blood cells, liver, and kidney, while the long T_2 behavior was exhibited by halothane in serum.

These more recent results have prompted a thorough review of the original paper by Evers et al.,⁴¹ and have led to a reappraisal of the pharmacological relevance of the T_2 behavior of volatile anesthetic agents in the brain. The area clearly requires further study.

3.4 Metabolism of Fluorinated Agents

Many of the previous ^{19}F MRS studies of halothane provided some data on the production of metabolites of the agent. Other groups have used the technique to study directly the metabolism of volatile anesthetics in the liver.⁴⁶⁻⁴⁸ This issue is of considerable importance, since reactive metabolites of halothane and other agents are thought to act as haptens and lead to rare but fatal immunologically mediated liver failure.⁴⁹ For example, Preece et al.⁵⁰ studied the metabolism of enflurane in the liver of rats anesthetized with thiobarbitone. They demonstrated an elimination $t_{1/2}$ of 76 min for enflurane in the rat liver, and showed that this figure could be reduced to 39

Figure 13 Superimposed ^{19}F MR spectra of brain isoflurane obtained at 4.7 T at different inspired concentrations of the agent, in spontaneously breathing (a) and artificially ventilated (b) animals. The apparent saturability of brain isoflurane at high inspired concentrations seen in (a) is a reflection of respiratory depression, since the spectra in (b) show a linear increase in brain halothane levels with inspired concentration. (Reproduced with permission from S. H. Lockhart, Y. Cohen, N. Yasuda, F. Kim, L. Litt, E. I. Eger II, L.-H. Chang, and T. James, *Anesthesiology*, 1990, **73**, 455)

min by pretreatment with isoniazid, which is known to enhance hepatic metabolism of enflurane (Figure 14). Similar studies may be useful in delineating pharmacogenetic differences in metabolism between individuals, or in elucidating the effects of drugs that enhance or inhibit the metabolism of volatile anesthetic agents. Data obtained from such studies may be quantitatively different, as in the studies by Preece et al.,⁵⁰ or show qualitative differences in metabolic pathways in different individuals or induced by different agents. Such processes could result in an increase or decrease in the production of toxic metabolites.

3.5 Clinical Studies

Clinical ^{19}F MRS studies of volatile anesthetics may have substantial advantages, since they enable the assessment of

Figure 14 Decrease in the normalized signal intensities (as a percentage of the initial total) of enflurane in the liver with time. The plots show the decay of the major and minor resonances in control (■, ◆) and isoniazid pretreated rats (●, ▲). Points and bars represent the mean $\pm$ SEM of four rats; the calculated $t_{1/2}$ values for signal decay are also shown. (Reproduced with permission from N. E. Preece, J. Challands, and S. C. Williams, *NMR Biomed.*, 1992, **5**, 101)

subtle cognitive dysfunction produced by trace residual anesthetic concentrations, and may be technically easier since the human head is larger, and the improved signal-to-noise ratio may enable more effective and specific volume selection. However, such studies also present considerable logistic and ethical problems. Menon et al.⁵¹ reported the use of ^{19}F MRS to study halothane in the brain of eight patients recovering from halothane anesthesia of short duration. A 6 cm surface receiver coil was used, and resonances attributable to halothane were observed in these patients up to 90 min after withdrawal of the anesthetic agent (Figure 15). Localized spectroscopy with two-

Figure 15 Decay of the ^{19}F signal intensity (arbitrary units) of halothane resonance with time after anesthesia in a patient where a single ^{19}F resonance was observed, and localized to the brain using a two-dimensional CSI sequence. (Reproduced with permission from D. K. Menon, G. G. Lockwood, C. J. Peden, I. J. Cox, J. Sargentoni, and J. D. Bell, *Magn. Reson. Med.*, 1993, **30**, 680)

Figure 16 Spectra acquired from the whole sensitive volume of a surface receiver coil in two patients recovering from halothane anesthesia. In both spectra the large resonance at 0 ppm arises from an external NaF standard. (a) The single resonance at +43 ppm is from halothane. (b) The two resonances at +38 and +41 ppm are clearly seen in the inset, where the peaks are enlarged. (Reproduced with permission from D. K. Menon, G. G. Lockwood, C. J. Peden, I. J. Cox, J. Sargentoni, and J. D. Bell, *Magn. Reson. Med.*, 1993, **30**, 680)

dimensional chemical shift imaging (CSI) showed that, although some of the signal arose from extracranial tissues, a substantial proportion arose from brain. The signal-to-noise

ratio for an unlocalized spectrum was typically 20 with data collection times of 2 min.

In seven patients a single resonance was seen with a mean ($\pm$ SD) chemical shift of +43.3 ($\pm$ 1.8) ppm, referenced to NaF at 0 ppm [Figure 16(a)]. This chemical shift is comparable to that observed in animal studies of halothane anesthesia. This resonance exhibited a T_1 value of 0.5–1 s, and a T_2^* (estimated from the linewidth of the resonance) value of 3.5–10 ms. In one patient two resonances were observed with chemical shifts of +38 and +41 ppm [Figure 16(b)]. These two resonances may represent halothane in two different chemical environments within the brain, since phantom studies showed that the chemical shift of halothane in different environments (such as water, olive oil, methanol, and lecithin) could vary to an extent that accounted for the two resonances seen. The two resonances observed in this patient had different T_1 values and linewidths (and, by implication, different T_2^* values). Intriguingly, the two-dimensional CSI localization in this patient suggested that the broader resonance at +38 ppm was confined to the brain, while the narrow resonance at +41 ppm arose from overlying scalp (Figure 17). Although susceptibility effects could not be excluded, it is at least possible that these two resonances represent halothane in two different tissues.

While the results discussed above do not resolve the problems discussed in earlier sections, they do demonstrate the feasibility of in vivo ^{19}F MRS studies of fluoroanesthetics in humans, and confirm several findings observed in animal studies. In further studies, Lockwood et al.^{52,53} have used ^{19}F MRS to study the pharmacokinetics of isoflurane in volunteers. They found two-compartment kinetics within the

Figure 17 Spectra from three contiguous planes of the head acquired during the course of a two-dimensional CSI sequence, the location of which is shown on the line diagram of a transverse image of the head. Note that the resonances from superficial and deep slices have different chemical shifts (+38 and +41 ppm, respectively) and linewidths. (Reproduced with permission from D. K. Menon, G. G. Lockwood, C. J. Peden, I. J. Cox, J. Sargentoni, and J. D. Bell, *Magn. Reson. Med.*, 1993, **30**, 680)

Figure 18 Isoflurane anesthesia in a volunteer during wash-in and wash-out.⁵³ The subject was unresponsive to verbal stimuli during the period between the two vertical dotted lines. (a) Partial pressure of isoflurane measured in inspired gas (upper continuous line), expired gas (lower continuous line) and arterial blood (solid circles). (b) Actual ¹⁹F MRS data in arbitrary units (solid circles) and the summed intensities from the two-compartment model calculated for the data (continuous line). The fast (broken line) and slow (dotted line) components of the model are calculated from the MR data. In (a) the calculated fast-compartment trace is largely identical with the experimental data and is not visible. (Reproduced by kind permission of Oxford University Press from G. G. Lockwood, D. P. Dob, D. J. Bryant, J. A. Wilson, J. Sargentoni, S. M. Sapsed-Byrne, D. N. Harris and D. K. Menon, Magnetic resonance spectroscopy of isoflurane kinetics in humans, Part II: Functional localisation. *British Journal of Anaesthesia*, **79**, 586–9 (1999).)

head with equilibrium half-times of 3.5 min and approximately 1 h with respect to expired isoflurane concentrations.⁵² Using critical fusion flicker frequency as an objective measure of the cerebral effect of isoflurane, they found evidence to identify the fast component as in brain tissue. Responsiveness to command was lost at a brain partial pressure of 0.3% isoflurane.⁵² It was concluded that these measurements exactly matched the predictions of the classical perfusion-limited model. These compartments showed decay half-times of 9.5 and 130 min, but the signal was too weak to localize the compartments spatially. If the fast compartment is assumed to be the brain then these results match the predictions of the classical perfusion-limited pharmacokinetic model of inhalation anesthesia (Figure 18).⁵³

1 INTRODUCTION

In the middle of the 19th century, a central debate about brain function revolved about the issue of whether the human brain processed all of its task as a single entity or function was compartmentalized. At about that time, an argument for the existence of regional specialization of human brain function was presented by Pierre Paul Broca.¹ Broca examined a patient who was unable to speak as a result of a stroke but was otherwise normal. Based on an autopsy performed subsequent to the patient's death, Broca concluded that the seat of the damage was an egg-sized lesion located in the inferior frontal gyrus of the frontal lobe in the left hemisphere; this general area is now commonly referred to as Broca's area, although its precise topographical extent remains ambiguous. This type of study and, later, intraoperative mapping efforts with electrodes were, until recently, the primary source of our information on functional compartmentation in the human brain.

Recent techniques using NMR permitted the acquisition of such information much more rapidly and with greater spatial accuracy, fueling explosive developments in the investigation of human brain function. For example, the language area first identified by Broca can now be visualized with unprecedented spatial resolution using functional MRI (fMRI), in data collection times that last only a few minutes. Figure 1 displays the three-dimensional result of such a study.² The functional map generated is superimposed on the anatomical image during a covert language task. In these figures, the gray scale anatomic images are either opaque, permitting the visualization of activation only on the outer cortical surface, or rendered partially transparent so that activation in the interior of the brain and within its numerous folds (sulci) are visible, albeit with diminished intensity.

These images are based on BOLD (blood oxygen level-dependent contrast), first described by Ogawa in rat brain studies³⁻⁵ and subsequently applied to generate functional images in human brain.⁶⁻⁸ Today, images like those shown in Figure 1 can be generated by the 1.5 T scanners that are often found in hospitals, provided that the scanner is equipped with appropriate hardware to perform fast imaging. These are relatively 'low' resolution images, in the several millimeter spatial domain, obtained with averaging over many executions of the

same task by a single individual. However, there have been studies beyond this type of imaging using significantly higher magnetic fields.

Shortly before the introduction of BOLD-based fMRI, efforts were initiated in three laboratories, Universities of Minnesota and Alabama, and the National Institutes of Health, to explore the possibility of using high magnetic fields (4 T) for human MRI. However, these high-field studies were initially met with skepticism, and the possibility of human imaging at magnetic fields much higher than 1.5 T was seriously questioned. This skepticism was not based on the existence of any experimental evidence; rather, it followed from concepts and theoretical considerations regarding the interaction of high-frequency electromagnetic waves with the conductive human body. These considerations had led prominent investigators in the field of MRI research, as early as 1979, to suggest that human imaging would not be possible beyond 10 MHz (~0.24 T).⁹ Of course, even clinical imaging is now performed at magnetic fields much higher than 0.24 T (up to 1.5 T), and recent work at 3 and 4 T has demonstrated that exquisite anatomical and functional imaging of the human head is achievable at these high fields. The efforts toward the development of fMRI at our site was performed only at 4 T, coinciding with the effort to introduce and explore the use of these high magnetic fields.

It is generally stated that the contrast-to-noise ratio (CNR) for the BOLD effect and hence for detection of activated areas increases at high fields, hence higher fields are better for fMRI. This may indeed be the case for some field strengths. A clear demonstration of this is illustrated in Figure 2, where mapping of the various functionally distinct regions within the visual cortex at 1.5 and 3 T depict larger areas of activation at the higher field strength. These are images of the flattened cortex. Similar functional maps have been published by Tootell and colleagues previously, mainly at 1.5 T.¹⁰⁻¹⁵

However, the field dependence of the BOLD-based fMRI is rather complex. At high fields, for example, the fractional signal change coupled to alterations in neuronal activity may actually become smaller than that observed at lower magnetic fields such as 1.5 T; however, the specificity of signal changes detected by MR in relation to the actual site of neuronal activation may be substantially improved. Such trade-offs between CNR and specificity will also depend on the details of data acquisition. Therefore, consideration of the BOLD mechanism is imperative in understanding the underlying field dependence of fMRI. This chapter starts with such a discussion and subsequently gives a few selected examples of accomplishments that remain unique to high-field fMRI.

2 MECHANISTIC CONSIDERATIONS RELEVANT TO FIELD DEPENDENCE

2.1 Extravascular Blood Oxygen Level-dependent Effects

Modeling of the effect of susceptibility gradients across vascular boundaries on MR signals have been considered by several groups, with similar conclusions.¹⁶⁻²⁴ If one considers an infinite cylinder as an approximation for a blood vessel with magnetic susceptibility difference $\Delta\chi$, then the magnetic field expressed in angular frequency at any point in space will be perturbed from the applied magnetic field ω_0 .¹⁶ Inside the

Figure 1 Three-dimensional, whole brain images of activation during a language task based on word generation from a phoneme. Subjects were presented phonemes and were asked to think of as many English words as they could that contained the phoneme until the presentation of the next phoneme. The gray scale picture is the anatomical image. In color is the superimposed functional map. Brain images shown are (a) left hemispheres (b) right hemispheres, and (c) at an angle where the left hemisphere and top of the brain are both partially seen. The extensive frontal cortex activity depicted in (a) largely defines the area of Broca and extends to area 46 as well. In (a)–(c), the anatomical images are opaque; consequently only activated regions that lie predominantly on the cortical surface are seen. Image (d) is identical to (c) except that the anatomical image was rendered partially transparent in order to ‘look through’ and see the activated regions that would normally be blocked from the view by overlapping cortex (e.g., regions within sulci). In these particular views, activity in the medial part of the brain and other areas are also apparent, albeit with diminished intensity, in addition to the extensive activity in the left hemisphere frontal cortex. (With permission from Erhard et al.²)

cylinder, the perturbation, $\Delta\omega_B$, will be given by:

$$\Delta\omega_B^{\text{in}} = 2\pi\Delta\chi_0(1 - Y)\omega_0\{\cos^2(\theta) - 1/3\} \quad (1)$$

At any point outside the cylinder, the magnetic field will vary, depending on the distance and orientation relative to the blood vessel and the external magnetic field direction, according to the equation:

$$\Delta\omega_B^{\text{out}} = 2\pi\Delta\chi_0(1 - Y)\omega_0\{r_b/r\}^2\sin^2(\theta)\cos(2\phi) \quad (2)$$

In these equations, $\Delta\chi_0$ is the maximum susceptibility difference expected in the presence of fully deoxygenated blood, Y is the fraction of oxygenated blood present, r_b is the cylinder radius, and r is the distance from the point of interest to the

center of the cylinder in the plane normal to the cylinder (Figure 3). Note that outside the cylinder the magnetic field changes rapidly over a distance comparable to two or three times the cylinder radius; at a distance equal to the diameter of the cylinder from the cylinder center, $\Delta\omega_B^{\text{out}}$ is already down to 25% of its value at the cylinder boundary.

If such a blood vessel is present in a given voxel, the magnetic field within this voxel will be inhomogeneous. The effect of this inhomogeneity in tissues can be understood in terms of *dynamic* and *static averaging*, the former arising as a result of the diffusive motion of the water molecules.

First, let us ignore the blood in the intravascular space (i.e., inside the cylinder) and focus on the *extravascular space* only. In BOLD-based fMRI, data are collected after excitation and an echo delay time TE in a gradient or a spin echo sequence.

Figure 2 Mapping eccentricity and motion versus stationary stimulus in the visual cortex. Images are presented as a flattened cortex. (a), (b) Data from an experimental mapping eccentricity; (c), (d) low-contrast moving stimulus versus stationary stimulus that activates areas MT and V3a. (a), (c) Data at 3 T, with statistical significances ranging from 10^{-5} to 10^{-15} . (b), (d) Data at 1.5 T analyzed with the same statistical criteria as in (a) and (c). Comparison of (a) and (c) and of (b) and (d) show the effects of magnetic field strength at the same statistical significance. (Figure supplied by N. Hadjikhani and R. Tootell)

Typical TE values used depend on the field strength and the specifics of the pulse sequence but, in general, range from ~ 30 to ~ 100 ms. If the typical diffusion distances during the delay TE are comparable to the distances spanned by the magnetic field gradients, then during this delay the magnetic field inhomogeneities will be dynamically time-averaged. Therefore, blood vessel size compared with the diffusion distances in this 30–100 ms time domain becomes a critical parameter in the BOLD effect (Figure 4). In this time scale, small blood vessels (e.g., capillaries) that contain deoxyhemoglobin will contribute

to the dynamic averaging and result in a signal decay that will be characterized with a change in T_2 time.^{17,18,25} In a spin echo experiment with a single refocusing pulse in the middle of the delay period, the dynamic averaging that has taken place during the first half of the echo will not be recovered. Of course, applying many refocusing pulses, as in a Carr–Purcell pulse train, or applying a large B_1 field (relative to the magnitude of the magnetic field inhomogeneity) for spin-locking during this delay will reduce or even eliminate this signal loss through dynamic averaging. In a gradient echo measurement,

Figure 3 A cylinder representing a blood vessel and the parameters that determine magnetic field at a point outside of the cylinder when the susceptibilities inside and outside the cylinder are not the same

dynamic averaging will occur during the entire delay TE . If the imaging voxel contains only small blood vessels at a density such that one half the average distance between them is comparable to diffusion distances (as is the case in the brain where capillaries are separated on the average by $25 \mu\text{m}^{26}$), then the entire signal from the voxel will be affected by dynamic averaging.

In considering the movement of water molecules around blood vessels, we need not be concerned with the exchange that ultimately takes place between intra- and extravascular water across capillary walls. Typical lifetime of the water in

Figure 4 Dynamic and static averaging regimes based on diffusion distances relative to the size of a compartment that differs in magnetic susceptibility from the surrounding tissue. The magnetic field gradients are most prominent in the vicinity of the compartments with different susceptibility, i.e., red blood cells, capillaries, and large blood vessels. For large blood vessels, diffusion distances are not large compared with vessel radius, and hence they do not lead to dynamic averaging

capillaries exceeds 500 ms,^{27–29} significantly longer than the typical T_2 and T_2^* values in the brain tissue and longer than the period TE typically employed in fMRI studies.

For larger blood vessels, complete dynamic averaging for the entire voxel will not be possible. Instead, there will be ‘local’ or ‘partial’ dynamic averaging over a subsection of the volume spanned by the magnetic field gradients generated by the blood vessel. However, there will be signal loss from the voxel through static averaging if refocusing pulses are not used or asymmetric spin echoes are employed. Following the excitation and rotation onto the plane transverse to the external magnetic field, a water molecule at a given point in space relative to the blood vessel will see a ‘locally’ time-averaged magnetic field that will vary with proximity to the large blood vessel. Therefore, the signal in the voxel will then be described by:

$$S(t) = \sum_k c_k e^{-TE/T_{2k}} (e^{-i\bar{\omega}_k TE}) \quad (3)$$

where the summation is performed over the parameter k , which designates small volume elements within the voxel, and c_k is a constant; the time-averaged magnetic field experienced within these small volume elements is $\bar{\omega}_k$ in angular frequency units. The summation over k , therefore, covers the entire voxel. Because $\bar{\omega}_k TE$ varies across the voxel, the signal will be

Figure 5 The susceptibility-induced R_2^* ($1/T_2^*$) in the presence of water diffusion plotted as a function of cylinder radius at three different values of frequency shifts. TE is 40 ms and the fractional ‘blood volume’ (i.e., volume within cylinder relative to voxel volume) is 0.02. (With permission from Ogawa et al.¹⁸)

Figure 6 The fractional signal loss ($\Delta S/S$) for spin echo versus a gradient echo image acquisition as a function of cylinder radius TE , 40 ms; frequency shift owing to susceptibility difference, 40 Hz; fractional ‘blood volume’ (i.e., volume within cylinder relative to voxel volume), 0.02. (With permission from Ogawa et al.¹⁸)

‘dephased’ and diminish with increasing TE . This signal loss occurs from static averaging. In this domain, if the variation ω_k over the voxel is relatively large, signal decay can be approximated with a single exponential time constant T_2^* .

Figure 5 illustrates R_2^* (i.e., $1/T_2^*$) as a function of the radius of the cylinder from modeling studies by Ogawa et al.¹⁸ In this calculation, all other relaxation mechanisms that can contribute to transverse relaxation of water protons are ignored; only the effect of the susceptibility difference between the cylinders and their surrounding is considered. The imaging voxel was divided into many cubes ($>10^6$) with an edge dimension L , each of which contained a single cylinder of length L . The volume of the cylinder (i.e., ‘blood volume’ b_v) relative to the volume of the cube is given by $(\pi r_b^2 L)/L^3$. Figure 5 displays the results as a function of cylinder radius and for a frequency shift ($\Delta\chi_0(1-Y)\omega_0$) equal to 32, 48, and 64 Hz, $b_v=0.02$ (simulating the capillary blood volume to total tissue volume ratio in the brain,²⁶ and TE of 40 ms (often used in studies at 4 T). Given the maximal susceptibility difference between fully oxygenated and fully deoxygenated blood⁵ and taking Y to be 0.6, typical of venous blood in the brain, the frequency difference $\Delta\chi_0(1-Y)\omega_0$ is calculated to be 43 Hz at 4 T. The data in Figure 5 demonstrate that at a radius less than ~ 5 to $10 \mu\text{m}$, depending on the magnitude of the frequency shift, R_2^* decreases because of dynamic averaging; the cylinder radius where this R_2^* decrease becomes apparent is smaller at larger frequency shifts as expected. Above $\sim 10 \mu\text{m}$, R_2^* is approximately independent of the radius as the static regime dominates for all $\Delta\chi_0(1-Y)\omega_0$ values considered in these calculations. These modeling efforts also suggest that deoxyhemoglobin-containing microvessels in the brain [i.e., capillaries ($5 \mu\text{m}$ mean diameter) and venules (which can be $2\text{--}20 \mu\text{m}$ in diameter³⁰)] would be in the ‘dynamic’ averaging regime. Note that the frequency difference between the intra- and extra-cylinder

compartments depends both on the applied external magnetic field B_0 and on the magnetic susceptibility difference $\Delta\chi$ between the cylinder and its surrounding. Consequently, either at very high magnetic fields or at very large values of $\Delta\chi$, the radius at which a transition occurs from static to dynamic averaging will shift to values smaller than the capillary size. Such large values of $\Delta\chi$ can be achieved even at 1.5 T with bolus injections of contrast agents.

Figure 6 illustrates the dynamic versus static averaging regimes and their dependence on cylinder radius (i.e., blood vessel radius) in a different way. In a spin echo study, static averaging will not come into play because the refocusing pulse will undo the ‘dephasing’ and ‘rephase’ the spins. Therefore, spin echoes will only be sensitive to small cylinder radii. For gradient recalled echoes, both dynamic and static averaging are, in principle, operative. However, for small cylinder radii, only the dynamic averaging regime will apply. Therefore, a plot of the ratio of fractional signal loss during TE (i.e. $\Delta S/S$) for a spin echo versus a gradient recalled echo will have a curve approaching unity as the cylinder radius approaches zero. At the other extreme, this ratio will diminish with increasing cylinder radius as dynamic averaging disappears and a static averaging regime dominates.

The net result of these calculations (again so far not considering the intravascular effects) yields the following terms for contributions to R_2^* :

$$R_2^* = \alpha \{ \Delta\chi_0 \omega_0 (1 - Y) \} b_{v1} \quad (\text{large vessels}) \quad (4)$$

$$R_2^* = \eta \{ \Delta\chi_0 \omega_0 (1 - Y) \}^2 b_{vs} p \quad (\text{small vessels}) \quad (5)$$

where α and η are constants, ω_0 is the external magnetic field in frequency units (rad/s) (i.e., $\omega_0 = \gamma B_0$), $\Delta\chi_0 \omega_0 (1 - Y)$ is the frequency shift owing to the susceptibility difference between the cylinder simulating the deoxyhemoglobin-containing blood vessel, b_{v1} is the blood volume for large blood vessels (veins and venules with a radius greater than $\sim 5 \mu\text{m}$ for 4 T) and b_{vs} is the small vessel blood volume (capillaries and small venules, less than $\sim 5 \mu\text{m}$ in radius, that permit dynamic averaging), and p is the fraction of active small vessels (i.e., filled with deoxyhemoglobin-containing red blood cells).

An important feature of Equation (5) is the fact that it varies as the square of the external magnetic field for small vessels where the effect is dominated by dynamic averaging. In contrast, the dependence on the external magnetic field is linear for large blood vessels because they are in the static averaging domain. Note, however, that even for the capillaries the quadratic dependence of the extravascular BOLD effect on ω_0 will not persist forever with increasing external magnetic field. At some very high external magnetic field strength, the frequency shift across the luminal boundaries of the blood vessel will be sufficiently large to displace even the capillaries into the static averaging domain, and hence to linear dependence on the applied magnetic field. At the present time, there is no experimental evidence as to what that field strength is, although results from our laboratory demonstrate that at 9.4 T there still exists an extravascular BOLD effect owing to dynamic averaging during activation (presented below).

Another important point that can be surmised from Equations (4) and (5) is that the BOLD effect will be proportional to three physiologic parameters: regional cerebral

blood flow (CBF) and oxygen consumption rate (CMRO₂) [since $(1-Y)=\text{CMRO}_2/\text{CBF}$] and regional blood volume. Neuronal activity is coupled to all of these physiologic parameters. It has been suggested that regional CBF increases while CMRO₂ in the same area is not elevated commensurably,^{31–33} resulting in decreased extraction fraction and lower deoxyhemoglobin content per unit volume of brain tissue.

Another important prediction of the modeling studies is that there are large and small vessel extravascular BOLD effects. This has implications with respect to the specificity of functional images generated by the BOLD effect. While capillaries are uniformly distributed in tissue and are sufficiently high in density, large venous vessels are not; consequently BOLD effects associated with large vessels will not be as closely correlated with the actual site of neuronal activity. This issue will be discussed in greater detail below.

2.2 Intravascular Blood Oxygen Level-dependent Effects

In the blood, hemoglobin is also compartmentalized within red blood cells and when the deoxy form is present, there are field gradients around the red cells. However, because the dimensions of red cells are very small compared with diffusion distances, the effect is dynamically averaged and becomes a T_2 effect only. The dynamic averaging in this case also involves exchange across the red blood cell membrane, which is highly permeable to water. Consequently, in the presence of deoxyhemoglobin-containing red blood cells, the T_2 value of blood decreases. This effect was noted by Thulborn and was shown to increase quadratically with field strength as expected from dynamic averaging owing to diffusion in the presence of field gradients.^{34,35} Therefore, even when we neglect the extravascular effect described above, the T_2 time of blood itself will change when the deoxyhemoglobin content is altered by elevated neuronal activity, and this will lead to a signal change in a T_2 - or T_2^* -weighted image. This effect will be present whenever the deoxyhemoglobin content has changed, potentially both in large and small blood vessels.

As discussed previously, an increase in cerebral blood volume (CBV) results in signal loss in the extravascular BOLD effect. If the extravascular BOLD effect is neglected and only the intravascular contribution is considered, the increase in CBV with elevated neuronal activity can be more complex. Essentially, the ratio of blood to tissue volume will increase in a given voxel when CBV is elevated during increased neuronal activity. If the blood T_2 time is longer than that of tissue, then the CBV increase will lead to a signal *increase* rather than the decrease that is always expected from the extravascular BOLD effect. At 1.5 T, blood T_2 can be calculated from:³⁶

$$(1/T_2) = 4.02 + 41.5(1 - Y)^2 \quad (6)$$

which yields ~250 ms for arterial blood ($Y \approx 1$), and 94, 129, and 176 ms for venous blood with $Y=0.6, 0.7$, and 0.8 , respectively. Experimental determinations give human arterial and venous blood T_2 times of 254 ± 26 ms and 181 ± 23 ms, respectively, at 1.5 T.³⁷ Compared with these blood T_2 values, cerebral tissues display T_2 values that range from ~70 to 90 ms at 1.5 T,³⁸ the longest value is associated with cortical gray matter. These investigators measured T_2 values at 1.4 T. These values are expected to be also valid for 1.5 T given the

relatively slow variation of T_2 with magnetic field strength for water in the brain. For example T_2 of cortical gray matter is 63 ± 6.2 ms at 4 T³⁹ as opposed to 87 ± 2 ms reported for 1.4 T.³⁸ At 1.5 T, the value of T_2 of both arterial and venous blood is longer than that of gray matter where the blood volume and alterations in blood volume coupled to neuronal activity are most significant.

Taking into account that the coefficient 41.5 in Equation (6) should be proportional to the square of the static field (except at very high magnetic fields), the T_2 time for venous blood can be calculated at other field strengths. At the same Y values, the predicted blood values for T_2 are approximately 4, 7, and 14 ms, respectively, for 9.4 T, in agreement with the experimentally measured values of ~7 to 8 ms in rat venous blood for a Y value in the 0.7 to 0.8 range (unpublished data from our laboratory). This rapid decrease in venous blood T_2 with increasing magnetic fields has significant implications for high-field fMRI studies and will be discussed below. At 4 T, where high-field human fMRI studies have so far been performed, blood T_2 is estimated to be 20, 31 and 63 ms for $Y=0.6, 0.7$ and 0.8 , respectively, using Equation (6); these values are comparable to or significantly less than the gray matter T_2 time of 63 ± 6.2 ms.³⁹

Blood contribution comes into the BOLD phenomenon in a second special way when blood occupies a large fraction of the volume of the voxel, in other words when a large blood vessel occurs in the voxel. When deoxyhemoglobin is present in the blood, the blood water will result in dynamic averaging in the gradients surrounding the red blood cells and it will behave as if it encounters the uniform magnetic field given by Equation (1). This will differ from the magnetic field experienced by the rest of the voxel. In the immediate vicinity of the blood vessel, the magnetic field will vary and it will approach a constant value in tissue distant from the blood vessel. For simplicity, we can neglect the gradients near the blood vessel and consider the voxel to be composed of two large bulk magnetic moments, one associated with blood and the rest with the extravascular volume. These magnetic moments will precess at slightly different frequencies, the difference in frequency given by Equation (1); therefore, the signal from the voxel will decrease with time as the two moments lose phase coherence. In this scenario, the signal can even oscillate as the phase between the two magnetic moments increases and then decreases. We will refer to this as a type 2 blood effect in fMRI. When a voxel only contains capillaries, the blood volume is ~2%;²⁶ hence, the type 2 blood effect cannot exist for such a voxel. However, when a large blood vessel or vessels are present in the voxel, blood volume can significantly increase and become comparable to or even exceed the tissue volume in the voxel. If, of course, the voxel is smaller than the blood vessel dimensions, and the entire voxel is occupied by blood, then here too the type 2 effect does not come into play.

Note that the type 2 blood effect and the extravascular BOLD effect in the static averaging regime are similar in nature because they both involve signal modulation owing to dephasing of magnetization within a voxel. The main difference is the presence of a large blood component and the lack of sufficient variation in resonance frequency within the voxel to approximate the signal modulation as an exponential signal decay in the type 2 blood effect. Similar to the extravascular BOLD effect in the static averaging domain, the type 2 blood

effect will be refocused in a symmetric spin echo and thus nullified. Consequently, it will *not* be present in purely T_2 -weighted BOLD and functional images derived from it.

Another important point is that this type 2 effect will diminish and even disappear at high magnetic fields because the T_2 value of blood gets very short and blood signal contribution becomes negligible.

2.3 Blood Oxygen Level Effects Detected in T_2 and T_2^* by fMRI

The origin of the signal intensity changes that are detected in T_2 versus T_2^* -based BOLD fMRI images, and hence the dependence on magnetic field of these effects, differ significantly, as can be surmised from the above discussion. These differences are summarized here.

The T_2^* -based BOLD signal can arise from both intravascular (blood) and extravascular effects originating from both large and small blood vessels. The relative contributions of these effects will depend on the magnetic field strength. In a T_2 -based BOLD fMRI map, the signal changes come from intravascular effects (i.e., blood T_2 changes), hence from both large and small blood vessels, and from an extravascular effect associated only with microvessels such as capillaries and small venules. The major difference is that the extravascular BOLD effect in a T_2 image can only arise from the microvasculature, whereas in T_2^* images, it can originate from blood vessels of all sizes.

It is often suggested that T_2 -based fMRI avoids a large vessel contribution. This claim is *not* correct because it ignores the intravascular blood-associated BOLD effect. At field strengths of 1.5 T, or even 4 T, there clearly exists a significant blood contribution to the BOLD effect during increased neuronal activity. At 1.5 T, T_2 -based fMRI maps are predominantly if not exclusively affiliated with blood T_2 changes, hence with intravascular space, as discussed in the next section. Such blood contribution can originate from both large and small blood vessels. Only at very high fields (e.g., 9.4 Tesla) is T_2 -based BOLD fMRI largely associated with the capillaries because intravascular blood contributions are suppressed by the very short T_2 value of blood (discussed in greater detail in the next section).

2.4 Experimental Studies

Early in the history of fMRI, it was demonstrated experimentally that the BOLD effect in human brain functional maps contained contributions from macroscopic venous blood vessels (i.e., vessels of ~0.5 mm or larger that can be visualized in MRI images) as well as from regions where no such macroscopic vessels were identified.⁴⁰ This has profound implications for the effective spatial specificity and spatial resolution that can be achieved with fMRI since large blood vessels do not exist at high density in the brain, where capillaries are common. Therefore, functional maps based on the macrovasculature can be significantly distant from the actual site of increased neuronal activity and thus misleading if high-resolution mapping in the millimeter or smaller scale is desired. The effect of the blood vessel size on BOLD will depend on magnetic field strength and the relative contributions of intra- and extravascular effects. These relationships can be experimentally evaluated.

The issue of extra- and intravascular BOLD effects has been experimentally examined using a Stejskal and Tanner⁴¹ gradient pair of either the same or opposite polarity, depending on whether gradient or spin echoes are used, respectively. Such gradients were first used to examine molecular diffusion; therefore, their use to alter the image signal intensity is often referred to as 'diffusion weighting' even though there are additional perturbations that arise from the use of such gradients.

In experiments employing the Stejskal–Tanner gradients, the important parameters are the magnitude and the duration of the gradient pulses and the time separation between them. Frequently, the results are evaluated in terms of a parameter b , which is equal to $(\gamma G \delta)^2 (\Delta - \delta/3)$ where γ is the gyromagnetic ratio ($\text{rad s}^{-1} \text{G}^{-1}$), G is the magnetic field gradient magnitude (G cm^{-1}), δ is the duration of the gradient pulse, and Δ is the separation in time of the onset of the two gradient pulses (where $1 \text{ G} = 10^{-4} \text{ mT}$). In simple isotropic diffusion, the MR signal in the presence of Stejskal–Tanner gradient, decays according to $\exp(-bD)$ where D is the diffusion constant. For flowing spins, b does not have such an immediately obvious physical meaning. If there is flow, the spins will acquire a phase that will depend on their velocity along the direction of the gradient and the gradient magnitude. Within vasculature, however, blood velocities are not uniform especially for vessels of large diameter. Furthermore, the blood vessels may change directions within a voxel, and there may be several different blood vessels with different flow rates and/or different orientations relative to the gradient direction. Since the blood signal detected from the voxel will be the sum of all these, the net result can be nulling of signal from flowing spins through dephasing.

The ability to nullify the intravascular signals by use of Stejskal–Tanner pulsed gradients provides the means to distinguish between intra- and extravascular BOLD effects in functional images. Such experiments have been performed at 1.5 and 4 T on humans. The studies at 1.5 T have indicated that most of the BOLD-based signal increase during elevated neuronal activity is eliminated by Stejskal–Tanner gradients, leading to the conclusion that most of the fMRI signal at 1.5 T arises from intravascular effects.^{42,43} This intravascular BOLD effect may be associated with macroscopic blood vessels since it is debatable whether the gradient pulses used can suppress intravascular signals from microscopic blood vessels such as capillaries and small venules.⁴⁴ As discussed above, the intravascular BOLD effect in functional brain imaging can arise from the change in blood T_2 time or from what we described as the type 2 blood effect. The latter is refocused by symmetric spin echoes and, therefore, can only be present in gradient recalled echo or asymmetric spin echo measurements. Given the fact that symmetric spin echo fMRI experiments at 1.5 T yield very weak effects compared with gradient recalled echo studies, the data acquired with suppressing the blood component suggests that most of the fMRI signal at 1.5 T arises from type 2 blood effects. The same conclusion was reached in high-resolution two-, or three-dimensional gradient recalled echo studies of motor cortex activation.⁴⁵

The effect of the Stejskal–Tanner gradients on brain tissue signal intensity at 4 T is illustrated in Figure 7a for a spin echo sequence. When activation studies were performed with such gradients at this field strength, ~60% of the 'activated' pixels disappeared at small b values but the remaining pixels persisted

Figure 7 (a) The effect on signal intensity of variations in the value of b in the human brain under diffusion weighting in a spin echo sequence. (b) Number of activated pixels in the human visual cortex during visual stimulation at 4 T before and during application of bipolar gradients with increasing b value. The sequence was a spin echo sequence yielding T_2 -weighted BOLD images. Residual signal intensity that persists at high b values can come only from the microvasculature. Data were from four subjects ($\circ$) or one subject ($\bullet$). (With permission from Menon et al.⁴⁶)

as the gradient strength was increased to very large b values (Figure 7b). This suggests that at 4 T extravascular and/or capillary-level intravascular BOLD effects exist during activation as well as a significant intravascular contribution associated with the macrovasculature. Note that we have grouped extravascular and capillary-level intravascular effects together because it is not clear whether these gradients are sufficient to nullify the intravascular signal from capillaries.

At 9.4 T, the effects of the Stejskal–Tanner gradients become even more interesting. In a T_2 -weighted fMRI study conducted in the rat brain (forepaw stimulation, symmetric spin echo with one 180° pulse), activation does not alter at all with changes from very small to very high b values (Figure 8).⁴⁷ The T_2 -based BOLD effects can only come from the blood through a change in the blood T_2 or from extravascular effects associated with capillaries and comparably sized venules. The gradient pair will suppress the blood effect, except possibly in capillaries and postcapillary small venules. Therefore, it can be concluded that at this very high magnetic field there exists a strong and dominant BOLD effect originating from microscopic vessels. Intravascular effects associated with a blood T_2 change is a priori not expected to be significant at this field strength because the T_2 value of venous blood is very short at 9.4 T (~ 5 ms),⁴⁷ as discussed above. Even arterial blood has a short T_2 time at this high magnetic field strength (~ 30 ms).⁴⁷

3 FUNCTIONAL IMAGING BASED ON CEREBRAL BLOOD FLOW

BOLD contrast relies on the interplay between CBF and CMRO₂ as well as blood volume, and, as such, it represents a complex response controlled by several parameters.^{18,21,23–25,48,49} Recent MR techniques, however, can also generate images based on quantitative measures of changes in CBF coupled

with neuronal activity.^{7,50–54} These CBF techniques rely on tagging the blood spins differentially within and outside of a well-defined volume. For example, in the FAIR technique^{51–53} frequency-selective inversion pulses are used to invert the longitudinal magnetization within a ‘slab’ along one direction (typically axial); in the absence of blood flow, the spins relax back to thermal equilibrium only by spin-lattice relaxation mechanisms characterized with the time constant T_1 . If flow is present, however, the relaxation becomes effectively faster as unperturbed spins outside the inverted slab flow in and replenish the net magnetization within the slab. Consequently, the effective spin-lattice relaxation in FAIR as well as other, similar flow-sensitive techniques^{48,51,53–58} becomes characterized by a shorter time constant, T_1^* , which is related to blood flow. It also follows naturally that if the inversion pulse in FAIR does not define a slab but inverts everything in the whole body (i.e., it is nonselective), blood flow does not enter into the problem. Therefore, in the FAIR technique, two images are acquired consecutively, each after a fixed delay period subsequent to the inversion pulse; in one, the inversion pulse is slab selective and in the other it is nonselective. The difference image generated from this pair is a flow-sensitive image.

One of the unique aspects of CBF-based functional maps is that macrovascular flow components can be selectively suppressed while sensitivity to microvascular flow and tissue perfusion changes is enhanced. In an experimental approach such as FAIR, this selective microvascular sensitivity is accomplished by changing the delay time after the initial inversion pulse and the subsequent signal excitation before image acquisition. In CBF-based functional imaging, longer delays (>1 s) emphasize microvascular flow and perfusion whereas shorter delays yield predominantly large vessel images.^{51,59} The former, of course, is highly desirable for generating functional maps. Herein lies the magnetic field dependence of CBF-based functional images. The T_1 time of tissue water gets significantly longer at high magnetic fields. Consequently, it is easier

Figure 8 Diffusion-weighted spin echo fMRI maps at 9.4 T with b values of 6.1 (a) and 438 s mm^{-2} (b) overlaid on one of the original consecutively acquired echo planar images (BOLD and diffusion weighted) collected during the functional imaging study. Coronal single-slice single-shot spin echo planar images of rat brain were acquired with a matrix size of 64×32 , a Field of View of $3.0 \text{ cm} \times 1.5 \text{ cm}$, a slice thickness of 2 mm, and TE of 30 ms. Somatosensory stimulation was used. The color bar indicates a maximum cross-correlation value from 0.7 to 0.9. Signal intensity (shown in background) was significantly reduced by bipolar gradients, as expected owing to diffusion. Localized activation is observed at the somatosensory cortex in the contralateral side of a stimulated forepaw. Foci of activation site (color) agree very well in both fMRI maps. (c) A Turbo FLASH image shows the region of interest. (d) Time courses of diffusion-weighted images within the region of interest. If the macrovascular contribution was significant, relative BOLD signal changes would decrease when a higher b value was used. However, relative signal changes remained the same in both images, suggesting that extravascular and microvascular components predominantly contribute to spin echo BOLD at 9.4 T

to detect the ‘microvascular’ flow and perfusion and suppress the macrovascular component (see Tsekos et al.⁵⁹).

In view of the macrovascular problems that can deleteriously affect BOLD images, the question arises as to why CBF-based images are not the preferred approach in generating functional maps. The answer is that the CNR is higher in BOLD images, and, in particular, rapid acquisition techniques covering the whole or a large subsection of the brain are yet to be developed with CBF-based methods. Unlike the CBF-based techniques, however, BOLD images can be acquired rapidly over the whole brain. Consequently, this approach remains the main method employed in fMRI applications.

4 SPATIAL SPECIFICITY

In fMRI studies, there are two reasons for concern regarding spatial specificity; one is the sensitivity to different size blood vessels and the presence of a macrovascular contribution, and the second is the spatial specificity of the physiologic and metabolic events that ultimately yield the functional images.

4.1 Early Blood Oxygen Level-dependent Responses

Optical measurements in animal experiments have demonstrated that the onset of task-related activation first results in signal changes interpreted as caused by an increase in deoxyhemoglobin content.^{60,61} This deoxyhemoglobin increase peaks at $\sim 3 \text{ s}$ after task onset and is subsequently reversed, ultimately resulting in a relatively large decrease in overall deoxyhemoglobin content. If CMRO_2 is elevated because of energy requirements of increased neuronal transmission, oxygen extraction and consequently the deoxyhemoglobin level will also be elevated provided the blood flow remains constant. In contrast, a CBF increase alone without any alterations in CMRO_2 will cause only a decrease in deoxyhemoglobin; if there is a difference in the metabolic and hemodynamic response times of these two processes, with the latter lagging behind, the time dependence of deoxyhemoglobin content in the ‘activated’ region will resemble the biphasic curve illustrated in Figure 9. Presence of early deoxygenation has been recently reported based on direct measurements of blood partial pressure of oxygen,⁶² indicating that there indeed exists an

Figure 9 Hypothetical time courses of cerebral blood flow (CBF) and oxygen consumption rate (CMRO_2) that would predict an early negative BOLD response

early increase in CMRO_2 that precedes the onset of enhancement in blood flow.

The early deoxyhemoglobin increase can also arise from a rapid elevation in blood volume before the onset of blood flow augmentation; such a volume increase would actually result in elevated oxy- and deoxyhemoglobin contents. A subsequent rush of oxygenated blood through enhanced blood flow would then decrease the deoxyhemoglobin level, provided oxygen utilization does not increase commensurately with CBF. The possible occurrence of such a rapid volume increase has been suggested by recent studies in the rat brain.⁶³

Malonek and Grinvald have argued that the early response is spatially more specific and defines better the columnar structure in the cat visual cortex examined in that study.⁶¹ In contrast, they suggest that the CBF increase is not as specific, flooding not only the active but also inactive columns and surpassing in spatial extent the actual area of activation by several millimeters. These claims suggest that the BOLD effect associated with the hyperoxygenated, high-flow phase during increased neuronal activity will also be spatially nonspecific over several millimeters, reflecting the spatial distribution of the CBF response. The question arises whether the early response associated with increased deoxyhemoglobin can also be detected as a negative signal change in BOLD-weighted MRI and whether this response can be used as a means of obtaining functional images with the MR approach.

An early negative response to activation was first reported by Hennig and colleagues using a MR spectroscopy method, monitoring signal from a relatively large voxel but with high temporal resolution.⁶⁴ Subsequently, first using averaging of data from a number of subjects⁶⁵ and later with single subjects, imaging studies documented the presence of a small but detectable early negative signal change, a 'dip', at high magnetic fields.^{66–70} Recently, the presence of this initial response was also observed in fMRI studies conducted in monkeys at 4.7 T;⁷¹ the magnitude and the time course was very similar to the human data obtained at 4 T.

Figure 10 illustrates the time dependence of BOLD contrast fMRI signal changes observed in the human visual cortex during and subsequent to a brief visual stimulation that lasted

2.4, 3.6, and 4.8 s.⁶⁷ In this study, T_2^* -weighted, gradient-recalled echo planar images were acquired rapidly covering only a few slices in the visual cortex, thus sacrificing spatial extent of coverage and spatial resolution in favor of time resolution. Furthermore, the brief stimuli were repeated several times (four to ten) and images were collected in synchrony with the stimulus presentation so that they could be averaged. The data revealed that during and following the brief visual stimulation period the BOLD-based fMRI signal initially decreased; this decrease was reversed at about 3 s, resulting subsequently in a large signal intensity increase (Figure 10). For the longer stimulation period, a signal intensity decrease below baseline was also seen towards the end of the time course; this 'late-phase', poststimulation decrease has been observed before, even in the very first fMRI papers, and may reflect a difference in the post-task temporal responses of blood volume⁷² and/or CMRO_2 values⁷³ returning to basal levels much more slowly than did the blood flow.

Figure 11 displays visual stimulation activation maps in the sagittal plane constructed from these data with the negative signal changes color coded in blue/purple colors and the positive response in red/yellow colors. Examining the images constructed from data collected during the early (negative) and the late (positive) response, we see that the early response is restricted to the anatomically well-defined visual area V1 (primary visual cortex) along the calcarine fissure while the later 'positive' BOLD image displays apparent 'activation' in areas distant from this region; in this study, these distant areas represent artifacts associated with the MR methodology, namely the macrovascular inflow effect, which has been already discussed. The macrovascular inflow effect was not suppressed in these images because they were rapidly acquired and were obtained using a surface coil both for signal detection and excitation; consequently, it was practically impossible to achieve the condition of 'full relaxation' between images that would have eliminated these artifacts without significantly sacrificing signal-to-noise ratio (SNR). The macrovascular inflow effect does not appear in the early images because it is absent owing to the slower hemodynamic response time. If the macrovascular effects are ignored and the functional maps around the calcarine fissure are compared, they are similar for the early negative and the later positive BOLD images. This observation has implications with respect to the spatial specificity of the functional maps generated by fMRI. It suggests that, provided the macrovascular 'inflow' artifacts are eliminated, the spatial specificity of the early negative BOLD-based maps and the later ΔCBF -dominated positive BOLD images are very similar at the resolution of this study (~3 to 4 mm isotropic). However, this study does not yet answer the question of spatial specificity raised by Malonek and Grinvald⁶¹ because the study is not conducted at a sufficiently high spatial resolution. It is likely that higher magnetic fields will be necessary to achieve greater spatial resolution with this early response because it is a very weak effect. The fact that it is detectable by BOLD-based fMRI, however, is significant both from a mechanistic point of view and for future developments in fMRI.

The early negative response has been examined further⁷⁴ and demonstrated to be linearly dependent on TE . The percentage signal change varied from individual to individual in the nine subjects studied, ranging between 0.38 and 0.95% at 21 ms TE and 0.93 and 3.2% at 45 ms TE at 4 T; however, in

Figure 10 Signal intensity time course for activated areas in the primary visual cortex (V1) for three different periods of brief visual stimulation. Initially, the signal decreased to a valley, which is the early negative response or dip; subsequently, the signal increased leading to a peak that corresponded to the positive BOLD effect employed in functional images. This positive BOLD effect is much larger in magnitude than the early negative BOLD effect. Note that the poststimulation undershoot is seen prominently only when the visual stimulation duration is 3.6 ms or larger. (With permission from Hu et al.⁶⁷)

each case, a linear dependence on TE was strongly evident. Figure 12 illustrates this linear dependence in a way that accounts for the intersubject variability. The presence of this linear response with TE is a priori expected if the initial negative change arises from a BOLD effect reflecting an increase in regional cerebral deoxyhemoglobin content.

If the early response arises from an elevated $CMRO_2$ prior to the onset of an increase in blood flow, then initial stages of this early response will be associated with the capillary bed. At later times, this deoxyhemoglobin alteration will show up in the venules and veins as a result of blood flow. Capillary BOLD effects scale as the square of the magnetic field, which would explain why this early negative response has not been detected or has been reported to be very small at 1.5 T. A recent study in our group was able to identify a small early response at 1.5 T in the visual cortex; comparison with the 4 T data suggests that the ratio of the peaks corresponding to the early negative and subsequent positive responses increased linearly with field strength. Given the large macrovascular contribution at both 1.5 and 4 T to the late hyperoxygenated state, only a linear dependence on B_0 is expected for this positive BOLD response. This suggests that the early response must increase quadratically with the magnetic field.

4.2 High-Resolution Imaging

The issue of spatial specificity and resolution of fMRI can also be addressed using specific experiments to map functionally distinct structures with well-defined organization and topography in the human brain. Early experiments introducing the fMRI methodology employed such a strategy and examined the hemispheric lateralization in brain function.^{6-8,75} For example, simple motor tasks are expected to be lateralized ipsilaterally in the cerebellum;⁷⁵ in other words, a simple motor task with the left or the right hand should predominantly activate the left or the right cerebellar hemisphere, respectively. This is in direct contrast to what is expected and observed in V1. However, detection of functional specialization with respect to hemispheric laterality only reveals the existence of a very coarse level of spatial specificity in a spatial domain that can be characterized as several centimeters; certainly, this level of specificity was demonstrated in the very first studies introducing fMRI.⁶⁻⁸ On a much finer spatial scale (e.g., millimeter and submillimeter), it is possible to examine activation of small subcortical nuclei and even that of lower-level neuronal functional organizations such as the ocular dominance columns (ODCs).

Figure 11 Functional images of visual stimulation constructed from (a) the early negative response (color coded in blue) and (b) the peak of the subsequent positive response (color coded in yellow/red). (With permission from Hu et al.⁶⁷)

The thalamus provides an excellent case for evaluating the question whether structures that are only a few millimeters in size can be accurately mapped by fMRI methodology. The thalamus contains several distinct, anatomically well-defined regions or nuclei. These nuclei serve as relay points for a remarkably large number of pathways. For example, retinal output projects mainly to the lateral geniculate nucleus (LGN), a small, subcentimeter nucleus located posteriorly and ventrally within the thalamus. In turn, the LGN activates V1.^{76–80} Detection of LGN activation by fMRI has previously been reported at 1.5 and 4 T field strength.^{81–83}

The LGN is functionally and spatially segregated and compartmentalized. Each of six LGN layers receives inputs from the specific visual field via the retina and then retinotopically signals to V1.⁸⁴ The specificity and resolution of fMRI can be examined by testing the feasibility of mapping the retinotopic organization within this small nucleus. We have recently conducted such a study using a checkerboard visual stimulus covering different sections of the visual field.⁸⁵ In particular, either upper or lower hemifield stimulation against a dark control period was utilized. This is expected to activate LGN bilaterally but not uniformly. Spatial differentiation reflecting the retinotopic relationship between the upper and lower visual fields was detected and distinguished within the LGN. This is illustrated as composite maps for four individual subjects in Figure 13. The LGN activation induced by the upper visual field stimulation (green and red pixels) was more inferior in location (closer to the hippocampal formation) compared with that induced by the lower visual field stimulation (yellow

Figure 12 Echo time dependence of the early negative response (dip) to activation. For each of nine individuals studied, an average percentage change was calculated for the three echo delays used. Subsequently, the percentage change for the dip at each echo time was divided by this average for that individual. Then, the 'normalized' percentage change at each echo time was averaged across the nine subjects studied. The data points represent the mean and standard deviation obtained from this procedure. The line is a linear fit to the data. (With permission from Yacoub et al.⁷⁴)

Figure 13 High-resolution fMRI mapping of lateral geniculate nucleus activation during the upper-field and lower-field red/black checkerboard visual stimulations (illustrated at the top of the figure). Images are in the coronal orientation. The activations in color represent composite fMRI maps obtained by combining the activation maps generated by upper-visual field versus a dark control period and lower visual stimulation versus a dark control period. The red pixels represent the overlap between these two activation maps. Yellow and green identify pixels activated only by the lower- and upper-field stimulation, respectively. (Adapted from Chen et al.⁸⁵)

and red pixels). This relationship is consistent with data obtained in the non-human primate visual system, which has been extensively studied using microelectrode recording⁸⁶ and selective lesions.^{87,88} Our results also illustrate that the LGN in humans behaves similarly to V1.¹⁰ However, the upper and lower visual field representations in V1 are anatomically separated by the calcarine fissure and are distinguishable without overlap. In contrast, they are continuous in LGN layers. This contributes to the partial overlap of LGN activation between the upper and lower visual fields (Figure 13).

From the LGN, geniculostriate projections to V1 continue to carry left or right eye input separately and terminate in layer IVC of V1, where they are arranged in a system of roughly parallel alternating stripes known as ODCs. In non-human primates and other vertebrates (e.g., cats), the organization of these columns has been studied by histological stains, autoradiography, and microelectrode recordings^{80,89,90} and by optical imaging of intrinsic signals.^{60,61,91–93} In humans, the ODCs have been demonstrated at autopsy in the striate cortex by histochemical staining for cytochrome oxidase,^{94,95} however, a noninvasive technique for examining human striate cortex organization on the scale of cortical functional subunits has not been available.

The hemodynamic-response mechanism that allows visualization of orientation columns and ODCs in awake monkeys by optical imaging of intrinsic signals demonstrates that corticovascular responses to visual stimuli can be localized to the columnar level in several mammalian species. In particular, the optical data demonstrate that, while the CBF response may not be specific at the ODC level,⁶¹ a deoxyhemoglobin difference across the active and inactive columns is generated presumably because of the enhanced CMRO₂ in the active but not the inactive column (Figure 14). This deoxyhemoglobin difference between the two columns should, in principle, be detectable by BOLD-based fMRI provided the technique has sufficient specificity as well as sensitivity (SNR) to achieve the required high spatial resolution. For example, if large vessel contributions dominate the BOLD contrast observed, specificity will be inadequate to detect ODCs.

For fMRI studies using clinically available hardware, ~3 mm in-plane resolution and ~5 mm slices are typical because of the limited SNR available without extensive data averaging. Using the same high-resolution fMRI pulse sequence with imaging hardware and parameters optimized at three different field strengths, we have found that the SNR at 4 T is at least four times higher than at the much more commonly available 1.5 T

Figure 14 Deoxy- and oxyhemoglobin response as a function of time during a brief period of visual stimulation in active and inactive columns in the cat visual cortex. The figure represents a summary of findings by Malonek and Grinvald.⁶¹

field strength.^{96,97} This increase is sufficiently large to attempt imaging of ODCs in human V1, which are approximately 0.8–1 mm on a side for a column and 5–10 mm long.^{94,95} Using a simple visual paradigm in combination with an optimized rf coil, head restraints, subvoxel image registration, and the enhanced SNR provided by 4 T field strength, it has been possible to demonstrate adjacent image pixels in human V1 that respond primarily to left or right eye photic input.^{98–101}

Figure 15a demonstrates a magnified picture of cortical ribbon along a sulcus in V1. The image plane is along the calcarine fissure and columns appear as rectangles of approximately 1 mm×1 mm separated by ~1 mm in the cortical gray matter. The color map represents pixels that had higher signal intensity during left eye monocular photic stimulation than during right eye stimulation. The dimensions of the ‘activated’ pixels are approximately 1 mm×1 mm or slightly smaller and are reproducible.^{98,99} The technique in this study was to first use a binocular stimulation and then to use alternating left and right monocular stimulation. The data were, however, analyzed by looking for statistically significant differences in pixel intensities for only the monocular stimulation period, ignoring the binocular stimulation completely. The pixels identified as activated during either the left or right eye monocular stimulation also showed activation for the binocular period, as they should

if they indeed represent ODCs as opposed to random statistical correlations.

Figure 15b demonstrates ODCs in the human brain from a more recent study at 4 T by Menon and colleagues.¹⁰² These images are obtained in the sagittal plane adjacent to the inter-hemispheric fissure and the ODCs are visualized as they appear on the cortical surface in this region of the visual cortex. The blue and red colors illustrate the columns associated with the two eyes. The columns are now seen along their long axis rather than in cross-section.

These data demonstrate for the first time that mapping of functional subunits in humans is possible in a noninvasive manner. The fMRI time courses show that the hemodynamic response at the ‘hyperoxygenation phase’ can be used at 4 T as a direct indicator of neuronal activity in cortical columns. This opens up the possibility of mapping specialized populations of neurons in humans that are not accessible to electrophysiological or other methods of invasive mapping. However, they do not yet resolve the issue of whether CBF increase coupled to increased neuronal activity and consequently BOLD response is spatially specific and selective at the column level. The column images illustrated in Figure 15 were obtained using alternating monocular stimulation. Therefore, columns would be detectable as long as there was a *difference* in the deoxyhe-

Figure 15 Detection of human ocular dominance columns (ODCs) during alternating monocular stimulation at 4 T. (a) Data obtained on a plane parallel to the calcarine fissure that intersects the ODCs perpendicular to their long axis. In this view, the ODCs should appear approximately as squares of 1×1 mm cross-section, separated by ~ 1 mm. There is a curving sulcus lined by the ODCs. (With permission from Menon et al.⁹⁹) (b) A more recent study at 4 T showing a sagittal plane adjacent to the interhemispheric fissure; the ODCs are visualized as they appear on the cortical surface. The blue and red colors illustrate the columns associated with different eyes. (With permission from Menon and Kim¹⁰¹ and Goodyear and Menon¹⁰²)

moglobin content of the inactive and active columns, and hence a difference in the BOLD effect, even if the deoxyhemoglobin content changed for *both* active and inactive columns, as illustrated in Malonek and Grinvald (Figure 14).⁶¹

The results summarized above demonstrate that, despite the presence of several potential problems, fMRI at 4 T has the specificity and sensitivity to map organizations in the millimeter or slightly smaller scale with the use of appropriate paradigms. This is unprecedented in human brain studies. We must emphasize the high-field aspect of all of the aforementioned high-resolution studies; to date, the ODCs have not been detected at lower field strengths.

5 SINGLE-TRIAL FUNCTIONAL MRI

Most fMRI studies utilize a ‘block’ design where periods of a control state are interleaved with periods of task performance and/or sensory stimulation. The control period itself may also require the subject to perform a task and/or be subjected to sensory stimulation. The images are generated by examining the difference between the control and the tasking periods. Each of these periods are relatively long, typically a minute or more, and the subject executes the task many times. The picture that emerges from such a study is a time average that blurs important information regarding the temporal evolution of the neuronal activity in different parts of the brain. Equally im-

portant, cognitive effects such as learning, alteration in strategy, etc. that evolve with repeated executions are also averaged into the final image generated.

fMRI is actually a realtime measurement. Single-slice fMRI images can be acquired in tens of milliseconds, adequate to monitor neuronal responses. Unfortunately, the temporal response of fMRI signals is dictated by the response of the vascular system, which is characterized with a time constant of seconds. This was demonstrated in one of the early fMRI studies¹⁰³ and subsequently confirmed in numerous other reports.^{67,104–108} However, even within this temporal regime, useful information on brain function can be obtained since numerous tasks and processes exist that necessarily engage the human brain for prolonged periods. In this temporal domain, signal changes in the fMRI images track the temporal evolution of stimulation or mental task performance very well, albeit with a shift in time or a delay that lasts several seconds. This capability permits the acquisition of fMRI data gated to a particular time point in stimulus onset or the instruction–execution sequence. In either case, this type of fMRI data collection is referred to as event-related fMRI.

In event-related fMRI, two distinct types of experiments have been performed. Buckner et al. acquired images gated to the onset of a task in a paradigm so that the temporal evolution of the fMRI signal during and following the execution of the task could be temporally co-registered and averaged following repeated executions of the same task.¹⁰⁹ However, such aver-

aging loses unique information associated with each execution of the task; subjects do not perform the same way each time because both brain function and performance is modulated by effects such as learning, alterations in strategy, errors, and habituation. In addition, when averages of single trials are performed, it is not possible to conclude much about the temporal differences that may be observed among different regions of the brain; such a difference was reported in the study by Buckner et al., where activation in left prefrontal areas involved in language were delayed ~2 s relative to extrastriate areas during a word generation task.¹⁰⁹ Of course, the human brain performs this task much faster than 2 s, and this time difference cannot really be attributed to differences in brain activation. Rather, differences must exist in the hemodynamic response of the fMRI signal in different regions of the brain. This distinction, however, cannot be made from the data alone in this study, and the interpretation of the results would be ambiguous in less obvious cases when this approach is utilized.

The second type of experiment was a true single-trial fMRI study achieved with the use of high magnetic fields (4 T).^{105,106,110–113} Intentionally and specifically, it was demonstrated that (at least at 4 T) there exists enough sensitivity to monitor fMRI signal evolution in a single execution of a task without averaging over many trials. This point is important. With this capability, it is then possible to perform many such single trial executions of a task and *not average them but rather to store them separately* and subsequently analyze and correlate the fMRI data with differences in aspect of the subject's performance (e.g., response time, errors, etc.). In this way, the hemodynamic response time differences can also be factored out and distinguished from temporal behavior of neuronal activity. An alternative approach is to average such single trials but using performance or response criteria to pool together only those response that are similar.

An example of a true single-trial study conducted at 4 T monitored the evolution of fMRI signals in the human brain before, during, and subsequent to an instruction and execution of a motor task (Figure 16). Both the single-trial fMRI signal intensity time courses in motor areas and the electromyograph (EMG) changes detected in the muscle are shown. The EMG showed no movements during the motor preparation period between Instruction and GO. Activation of the primary motor area and of the supplementary and premotor areas were observed during motor execution and preparation. These data are virtually identical to electrode recordings taken from the corresponding areas in a monkey cortex during execution of the same task, except that the fMRI data are displaced in time by seconds relative to the actual time of neuronal activity. The data presented in Figure 16 also illustrate the sensitivity of the high-field fMRI method. Like the electrode recordings from primates, the fMRI data demonstrate that V1 is active during the motor preparation period. This, however, has been a controversial issue with humans because positron emission tomographic studies did not reveal activation during such motor preparation.¹¹⁴ In the high-field fMRI study, this activation is detectable in a single execution of the task.

This type of true single-trial experiment was also utilized to correlate aspects of activation with task performance.^{106,113} The paradigm employed was the 'mental rotation' task of Shepard and Metzler.¹¹⁵ The subjects were presented with drawings of

Figure 16 A single-subject, single-trial fMRI (without averaging) study showing time courses in three regions of the brain together with the electromyograph (EMG) recording of muscle movement during a visually instructed delayed cued four-finger movement task. The presentation lasted 2.1 s and the GO signal was given at 9.1 s. M1, contralateral primary motor area; PM, bilateral premotor area; SMA, bilateral supplementary motor area. (With permission from Richter et al.¹¹¹)

three-dimensional objects, examples of which are illustrated in Figure 17. In each task, a pair of objects were presented; they were either identical or mirror images and they were rotated relative to each other through varying degrees. The subject had to identify whether the pair was identical or a mirror image and report it by pressing one of two buttons. In this task, subject's response time depended on the angle through which the two objects were rotated relative to each other. The experiment started with the subject looking at similar but identical two-dimensional objects. When ready, the subject commenced the scanning process by pressing a button. The three-dimensional objects were shown and the subject made a decision; after a suitable delay to allow for the hemodynamic response to return to basal levels, the process was repeated. Figure 18 displays signal intensity curves from the parietal lobe from two trials where the response time of the subject was different. The width of the response was evaluated for correct response only with respect to the response time. In each individual, linear correlation was found. However, the intercept corresponding to a response time of zero was significantly different for the different individuals, presumably reflecting fundamental differences in the hemodynamic response to elevated neuronal activity among individuals. When this subject-dependent variable was subtracted, each single-trial, single-subject data point for all subjects yielded an excellent correlation with response time (Figure 19).

One potential confounding problem with such single-trial fMRI studies is the presence of various types of spatiotemporal patterns in the fMRI signals even under basal 'resting' conditions. The T_2^* -weighted MRI signals fluctuate with heart beat and respiration, although fluctuations can be removed from the fMRI data.^{116–121} When cardiac and respiratory fluctuations are suppressed, fMRI signal from resting human brain still exhibits low-frequency oscillations at about 0.1 Hz.^{121–124} Near-infrared

Figure 17 The paradigm in a true single-trial 'mental rotation' study. (With permission from Richter et al.¹⁰⁷)

optical studies also show this slow oscillation. Therefore, techniques that can separate the fMRI data into its various components (e.g., Mitra et al.¹²¹) and in the process significantly improve effective SNR for detection of function will play a crucial role in mapping brain function, particularly in single-trial fMRI studies with temporal resolution.

6 CONCLUSION

Since its introduction, fMRI has rapidly evolved to become the most significant method for investigating human brain function, and unique accomplishments have been realized at high magnetic fields. However, it must be realized that high magnetic field MRI instruments are not optimized and refined machines as clinical scanners. Presence of a high-field magnet does not guarantee superior functional imaging results; instead,

Figure 19 The width of the fMRI response (in Figure 18) versus performance data from all subjects subsequent to removal of the time zero intercept. Each point represents a true single trial in a single subject (no averaging). (With permission from Richter et al.¹⁰⁷)

advantages that are inherent in the high field for functional mapping can easily be lost through instrumentation imperfections. Therefore, improvement in high-field instrumentation are essential for future expansion of these fMRI applications. Additional refinements in data collection schemes, motion correction, and statistical methods for data analysis, which are areas that are being actively pursued, will undoubtedly improve the already impressive capabilities of this methodology.

1 INTRODUCTION

Since 1990, interest has grown rapidly in MRI methods for mapping human brain function. These methods have good spatial and temporal resolution, and are completely noninvasive. As a result, repeated single-subject studies are feasible, allowing new types of experiments in cognitive neuroscience to be formulated. In addition, there are many potential clinical applications.

Functional brain mapping involves the visualization of local physiological changes within the brain that are associated with activation of the visual, motor, or other brain systems. The technique that has so far contributed most to functional brain mapping is positron emission tomography (PET).¹ These PET studies rely on the detection of changes in local hemodynamics that are associated with cerebral activation; in particular, there are changes in regional cerebral blood flow that can be mapped with PET through the use of ¹⁵O-labeled water. The MRI studies of functional activation that have recently been described also rely on hemodynamic changes, and on the detection of signals from water. However, in contrast to PET, the signal is from the protons of the water and the effects are observed without any need for radioisotope labeling. Instead, the detection of activation relies on perturbations of the water magnetization that are associated with the hemodynamic changes.

The first brain activation study using functional MRI involved the administration of the paramagnetic contrast agent Gd-DTPA to act as a marker of cerebral blood volume.² This investigation of the human visual cortex used a visual stimulus paradigm that, on the basis of PET studies, produces changes in regional cerebral blood flow of about 30–50%. Echo planar MR images were collected at intervals of 750 ms,

before, during and after injection of Gd-DTPA, which was administered as a bolus into the antecubital vein. As the Gd-DTPA passed through the brain, it produced a transient reduction in water signal intensity because of its magnetic susceptibility effects. From the time course of the signal changes, it was possible to generate images that reflected relative cerebral blood volume. The imaging procedure was carried out under control conditions, and also during visual stimulation produced by goggles that generated 8 Hz patterned flashes. Subtraction of the control from the activated blood volume image revealed those areas in which there was a change in blood volume associated with the task activation. These areas corresponded to the primary visual cortex.

As it happened, this initial activation study was very rapidly superseded by an alternative MRI approach which had the major advantage that no extrinsic contrast agent was required. It had been known for some time that there were several mechanisms whereby changes in blood flow, volume, and oxygenation can influence signal intensities without any requirement for exogenous agents, and it soon became apparent that activated regions of the human brain could be visualized using such intrinsic contrast mechanisms. In these studies, particular interest has focused on T_2^* -weighted signal intensity changes that have been attributed primarily to changes in local venous blood oxygenation, in particular to the effects generated by the paramagnetic iron centers of deoxyhemoglobin. There is a long history to NMR studies of this compound, and some of the salient points are described briefly below.

2 CONTRAST MECHANISMS IN FUNCTIONAL MRI

2.1 Blood Oxygenation Level Dependent (BOLD) Effects

It has long been known that the magnetic state of hemoglobin in red cells is dependent on oxygen saturation; with deoxygenation of hemoglobin, the electron spin of the heme Fe^{2+} changes from a diamagnetic state to a paramagnetic state. As a result, deoxygenated blood is more paramagnetic than oxygenated blood, the difference being about 0.2 ppm. There are magnetic susceptibility effects associated with this paramagnetism, and therefore local field gradients are generated in and around the blood vessels. These cause signal attenuation in T_2^* -weighted images, which is not confined just to water within the vessels; it can extend significantly into the surrounding tissue. As a result, there may be substantial signal changes associated with changes in oxygenation state, even if the blood volume is relatively small.

In the early 1990s, a number of animal imaging studies were published, in which it was demonstrated that these magnetic susceptibility effects could be exploited as a means of detecting oxygenation changes in the brain^{3–5} (see Figure 1). In particular, T_2^* -weighted images showed a reduction in signal intensity under conditions of reduced oxygenation, i.e. under conditions where there are increased susceptibility effects associated with the presence of deoxyhemoglobin. Before very long, studies were carried out in humans, using T_2^* -weighted imaging sequences^{6–8} that showed focal changes in signal intensity in response to visual tasks. In the work of Kwong et al.,⁶ subjects experienced visual stimulation for periods of 30 s,

Figure 1 Sequential coronal difference images of a cat brain, at 3-intervals. The cat was subjected to respiratory anoxia from images 20–40. Image 20 was subtracted from each of the others to give this demonstration of contrast changes. The development of hypoxemia is well seen as a darkening, predominantly in gray matter, and the overshoot on recovery is also clearly visible. The first image shows enhancement of cerebrospinal fluid due to the completely unsaturated condition of the spins at the outset of scanning. Images were obtained using a 2.0 T GE Omega, 45 cm bore, MR scanner. (Reproduced by permission from Turner et al.⁵)

interspersed by equal periods of darkness, while echo planar gradient echo images of a section passing through the primary visual cortex were obtained at 3 s intervals. When a control image was subtracted from each of the time-series of images, the resulting difference images showed unequivocal increases in intensity in the visual cortex, correlating very well with the visual stimulus. A lag time of 6–9 s was noted between onset of stimulation and rise to maximum of the difference signal, reflecting the timescale of the hemodynamic changes associated with activation.

It is significant that a rise in signal can be observed during visual stimulation, indicating a relative decrease in the concentration of paramagnetic deoxyhemoglobin. This confirms earlier work using PET⁹ in which the measured rise in oxygen uptake rate during visual stimulation was found to be much smaller than the rise in blood flow. Earlier observations during neurosurgery (see, for example, Penfield¹⁰) had also demonstrated that the blood leaving active cortical regions is brighter red, i.e. more oxygenated, than normal, as a result of this mismatch between demand and supply.

The contrast in T_2^* -weighted images is generated because gradient echoes do not refocus the dephasing effects of local field homogeneities associated with the presence of deoxyhemoglobin. If spin echoes are used instead of gradient

echoes, then such dephasing effects will be refocused, provided that there is no significant diffusion of the water molecules through the field gradients. This explains why T_2^* -weighted images are more sensitive than T_2 -weighted images to the effects of brain activation. However, if the water molecules diffuse through local field gradients during the echo time TE , then this will result in imperfect refocusing and hence to signal loss in T_2 -weighted spin echo sequences¹¹ (see also, earlier ^1H NMR studies of red cell metabolism¹²). Because water molecules can only diffuse a small distance in an echo time that may be of the order of 60 ms, this diffusion-dependent mechanism of signal loss should be more effective when the distances that characterize the gradients are small. Within the blood vessels themselves, these distances are indeed small, because the localization of deoxyhemoglobin to red cells results in local field gradients in the periphery of each individual cell. In the adjacent tissue, however, the dimensions characterizing these local gradients should be determined by the dimensions of the vessels. Therefore it can be anticipated that, in comparison with large draining vessels, small vessels such as capillaries should produce relatively large diffusion-dependent T_2 effects in the adjacent tissue. This has been explored as a means of distinguishing between the effects of large and small vessels (see below). However, it needs to

be borne in mind that changes in oxygenation in vessels of size comparable to a voxel will result in large signal intensity changes even in T_2 -weighted images.

2.2 Flow Effects

In theory, the water signal intensity can be affected by many hemodynamic effects, including changes in blood arterial oxygenation, blood volume, blood flow, hematocrit, tissue oxygen uptake, and possibly blood velocity. Indeed, the initial study of Kwong et al.⁶ highlighted not only T_2^* -dependent effects, but also T_1 -dependent effects that could be attributed to the direct influence of changes in local blood flow that were associated with activation. There is considerable interest in the influence of blood flow on signal changes associated with task activation, and numerous investigations have been concerned with distinguishing between flow and oxygenation effects (see, for example, Frahm et al.¹³).

One approach to visualizing flow effects involves the use of arterial spin tagging, using saturation or inversion of inflowing spins as a magnetic label. For example, if spins in the neck region are selectively inverted, then arterial flow will carry these labeled spins into the brain tissue and hence influence the observed signal from brain water. Comparison of the data obtained with and without this labeling procedure permits measurements of regional perfusion to be made. The signal change resulting from the magnetic labeling depends upon a number of factors, including the perfusion rate, the T_1 value of the tissue water, and any relaxation of the labeled spins during the time that they take to travel from the labeling plane to the detection volume. This approach has been used for the quantitative measurement of cerebral perfusion, initially in small animals, and more recently in man.¹⁴ Although the method has a number of well-recognized problems, it does offer a very promising approach to the noninvasive investigation of cerebral perfusion and of changes in perfusion associated with task activation and with disease processes.

A related method, termed EPISTAR, has recently been used to obtain qualitative maps of cerebral blood flow, with spatial resolution of $2 \times 2 \times 2$ mm.¹⁵ This method is an echo planar imaging modification of a time-of-flight angiography technique. It involves the alternate acquisition of two echo planar images with and without a radiofrequency inversion pulse applied to inflowing arterial spins. Image subtraction provides a picture of large proximal vessels when short inflow times are used, while progressively more distal portions of the tagged vessels are seen as the inflow time is lengthened. At these longer inflow times, the images represent a qualitative map of cerebral blood flow. The acquisition of such images also provides a means of visualizing activated regions of the brain.

3 IMAGING METHODS

Functional MRI studies generally involve the acquisition of data during a series of interleaved periods of rest and stimulation, each of these periods typically lasting about 30 s. Rapid imaging methods are therefore required. These divide into two categories: methods that use a series of low flip-angle excitation pulses (e.g. FLASH, Turbo-FLASH etc.),¹⁶

and methods which use a single excitation pulse (echo planar imaging).¹⁷ While both have proved successful, there is an increased tendency toward the use of echo planar imaging, which permits imaging of a complete slice in a time of 60–100 ms. With an imaging time of 100 ms, a complete multislice data set covering the whole brain can be obtained very rapidly (data from 30 slices could be acquired in 3 s), and it seems likely that multislice echo planar imaging will become the preferred method for the majority of functional MRI studies of the brain.

4 SOURCES OF ARTIFACT

In any magnetic resonance study, it is important to appreciate the various ways in which artifacts can influence the appearance of spectra or images. This is particularly true in the case of functional brain mapping methods, which suffer from certain problems which can give false positive results, or obscure the effect altogether. It must be understood that the signal changes of interest are usually not much larger than the thermal and physiological noise that inevitably accompany MR images of living tissue, so that equipment stability is of great importance. But two other issues have been the subject of controversy in the literature. These relate to the precision of localization of neural activity, and to artifactual image differences associated with subject motion.

4.1 Localization

Changes in signal intensity may be observed as a result of hemodynamic changes that are associated not only with capillaries, but also with larger draining vessels (see Lai et al.¹⁸). The draining vessels may be situated a long way 'downstream' of the activated tissue, and on task activation they may give rise to changes in signal intensity in regions that do not correspond directly to the regions that are actually activated, particularly with MRI sequences that are sensitive to flow velocity. For this reason, it is essential to establish, by one means or another, that the location of the observed signal changes does indeed reflect the focally activated regions. There are several ways in which this might be achieved. One method is to combine functional MRI with angiographic techniques, so that the regions of increase in signal intensity can be compared directly with the anatomical location of the draining vessels. Alternatively, the signal from these vessels may be suppressed by using imaging sequences that give reduced signal from regions of high flow. In addition, multislice techniques that effectively give a three-dimensional activation pattern should help to establish the source of the signal increase. Finally, it has been pointed out that the combination of T_2 -weighted and T_2^* -weighted imaging should help to distinguish between large and small vessels (see above), T_2 -weighted and T_2^* -weighted effects becoming more similar as vessels become smaller.^{19,20} In practice, there is a lot to be said for visualizing both the activated regions and the hemodynamic changes in the draining vessels, and the best approaches will no doubt preserve both types of information.

Further information about the possible importance of downstream effects, and also about the extent to which delivery of blood to brain tissue is spatially matched to

the increased demand, is available from other techniques. In particular, optical imaging methods, using a cranial window in animal models, or intraoperatively in human subjects, can provide information of direct relevance to the interpretation of functional MRI data.^{21,22}

4.2 Subject Motion

To visualize task-related regions of increased signal, the earliest functional MRI studies relied on single or averaged image differences between experimental and control conditions. While this method has the merit of explicitness and simplicity, it takes no account of spatial variations in image noise, and it is extremely vulnerable to head motion temporally correlated with the experimental task.²³ Normalization of the image difference by division of the difference at each pixel by the standard error of the mean in that pixel, to give a z score, accounts for artifacts caused by large intensity fluctuations related to cardiac or respiratory cycle. Misregistration artifact, however, may continue to confound the results. Clearly, either the brain must be rigidly fixed in place during each experiment, or a robust means of reregistration of images must be employed. Rigid head fixation may entail considerable discomfort, though a number of workers have successfully used bite bars. Image reregistration can be performed either by noting fiducial changes in head position during a study, and applying the required rotations and translations to the images afterwards, or by using internal image features and least-squares search procedures to determine post hoc the corrections needed. The iterative algorithm of Woods et al.²⁴ has been successfully used by a number of workers (e.g. Tyszka et al.²⁵), and very recently a faster, more robust, and more accurate algorithm has been developed.²⁶ Any such algorithm requires the acquisition of multislice image data to specify fully the three translations and three rotations characteristic of solid body displacement. This encourages the use of echo planar imaging (EPI) methods for functional MRI which, as mentioned above, can obtain images of the complete brain within 3 s.

5 IMAGE ANALYSIS

Once images have been coregistered, there are a variety of methods for extracting significant activated regions. Maps of F score, z score or Student's t score can be used, but only for images acquired with a repeat time of more than about 10 s, since the slowness of the hemodynamic response (about 6–10 s) introduces temporal correlations into the data, which reduces the number of degrees of freedom in each image. When images are acquired more rapidly, it is preferable to calculate the cross correlation between the time series data in each pixel with a suitably smoothed representation of the time variation of the task, the so-called contrast function.^{27,28} As a rule of thumb, a correlation coefficient r of >0.5 can be considered highly significant.

A number of workers have explored the use of non-parametric measures of signal change significance. Use of Kolmogorov–Smirnov statistics has attracted attention, but as the character of the image intensity distributions in functional MRI becomes more fully investigated, this approach is likely

to become less popular. Of greater importance is the increase in statistical power obtainable by including the spatial correlation between activated pixels,²⁹ which has not yet been fully explored in the context of functional MRI.

6 BRAIN FUNCTIONS STUDIED

Since the discovery of BOLD contrast in 1989, MR studies of human brain function have expanded very rapidly. As an index of this growth, at the Annual Meeting of the Society for Magnetic Resonance in Medicine in 1991 there was one presentation mentioning (and introducing) functional MRI. In 1992, at the next meeting, there were 21 presentations dealing with functional MRI, and 94 in 1993. At the corresponding meeting in 1994 there were more than 120 such presentations. Much of this early research has been published only in the form of long refereed abstracts for these meetings. Similar growth rates have occurred in submissions to the Society for

Figure 2 Areas V5/MT of occipital cortex specialized for motion perception. Protocol consisted of alternate presentations of still and moving visual grids, separated by rest periods of darkness. Multislice functional MRI was performed using echo planar imaging (TR 3 s, TE 40 ms) at 1.5 T, with a surface radiofrequency receiver coil at the back of the head to improve signal-to-noise ratio. (a) Map of echo planar imaging functional data, processed to give a Kolmogorov–Smirnov statistic, superimposed on a high-resolution structural MR oblique axial scan. Areas responding specifically to the moving grid are indicated by arrows. (b) Plots of time course data of regions of interest in V1 and in V5, showing the lack of response in V5 to a static object. (Figure provided by R. Tootell)

Figure 3 Brain activations in axial slices obtained with echo planar imaging at 1.5 T. The simple task consisted of flexing and extending all four digits together, while the complex task involved tapping each finger to the thumb sequentially in a repeating sequence. The imagined task required subjects mentally to rehearse this complex task without actual finger motion. Active areas were determined using a correlation technique, and were superimposed in color on a gray-scale high-resolution structural scan. (Figure provided by Rao et al.³⁴ summarizing their results) (SMA denotes supplementary motor area; M1 denotes primary motor cortex; S1 denotes primary somatosensory cortex)

Neuroscience annual meetings. In view of the current relative crudity of tools for registration and statistical analysis of functional MRI data, as already noted, the findings in many of these studies must be regarded at this stage as provisional but highly suggestive. For these reasons, we provide just a brief summary of the findings so far.

The study of the primary visual and motor cortices provides an appropriate means of establishing and validating this new method of functional neuroimaging, partly because these systems are relatively well characterized. Numerous studies have now been reported, including, for example, investigations of hemispheric asymmetry and handedness.³⁰ Another advantage of investigating these cortical areas is that the hemodynamic changes (and hence signal intensity changes) associated with the visual and motor tasks are likely to be considerably greater than those associated with higher cognitive functions. One of the main requirements is to establish the extent to which such higher functions are accessible to investigation by MRI. Initial studies, for example observations involving word generation,^{31–33} mental imagery (e.g. imagining of motor and visual tasks^{34,35}) and other cognitive tasks (see, for example, Kim et al.³⁶) appear encouraging, as illustrated by the studies shown in Figures 2–5. However, a great deal more work still needs to be carried out in order to establish the sensitivity of MRI to the wide range of cognitive tasks that are of interest to the neuroscience community.

The demonstration that standard 1.5 tesla systems can be used for at least some applications of functional imaging, including simple motor and visual task activation studies (see, for example, Connelly et al.³⁸) has greatly facilitated the use of functional MRI for clinical as well as the more neuroscientific applications. One clinical area of interest relates to neurosurgical removal of lesions that are close to the primary sensory or motor cortex. It can often be difficult

Figure 4 Functional maps of dentate activation during visually guided finger movements (a) and a cognitive puzzle task (b). The color-coded functional map is superimposed on a T_2^* -weighted image in gray scale. The dentate nuclei in the cerebellum are dark crescent-shaped regions with low background signal due to iron deposit. C, dentate contralateral to the moving limb; I, dentate ipsilateral to the moving limb; D, dorsal; V, ventral. For tasks, a small lightweight pegboard with nine holes was used. Subjects simply moved pegs for visually guided movements and tried to solve a pegboard puzzle for the cognitive task. All seven subjects examined showed a large bilateral activation during the cognitive task. The activated area was 3–4 times greater than that seen during the visually guided movements. These support the concept that the computational power of the cerebellum is applied not only to the control of movements, but also to cognitive functions. Data were obtained using a FLASH-type functional MRI sequence at 4.0 T. (Reproduced with permission from Kim et al.³⁶)

to predict the exact location of these primary cortical areas, due to normal biological variation and the distorting effects of the lesion itself. In order to permit maximal resection of such lesions, cortical mapping is performed. Until now, this has required direct electrical stimulation of the brain, often during an awake craniotomy. Using functional MRI, it is now possible to carry out noninvasive presurgical mapping of the sensory and motor cortex.³⁹ The functional MRI maps can be validated by comparison with the standard intraoperative cortical mapping procedures, and once the MRI method has been extensively validated in this way, then it could have major implications with respect to preoperative planning and to counseling of patients with lesions in these areas of the brain.

Functional MRI could also be of value in the investigation of patients with epilepsy, for preliminary studies have shown that the technique can be used to map the cortical activation that occurs during focal seizures. In these studies of a boy suffering from frequent partial motor seizures, functional MRI revealed sequential cortical activation in structurally abnormal regions of the brain.⁴⁰ The activation was observed with

Figure 5 Effect of hand training on area of activated motor cortex.³⁷ Two finger-tapping tasks were performed during the same functional MRI study, one unrehearsed and the other practised for 10 min per day. After 2–4 weeks the trained task activated a greater number of pixels, as shown. Echo planar imaging data (TR 2 s, TE 25 ms) at 4 T are projected as a z map in color on a high-resolution structural scan. Also shown are time course data from an area of cortex that activated much more for the trained task than for the untrained task, and from an area where the amplitudes of activation were more equal

each of five consecutive clinical seizures, and was also seen during a period that was not associated with a detectable clinical seizure. This latter finding, together with the time dependence of the signal changes that were observed, opens up the possibility of using functional MRI to detect not only the seizures themselves, but also subclinical or interictal events. The technique may therefore find relatively widespread application in the investigation of patients with intractable seizure disorders.

7 DISCUSSION

The scope of magnetic resonance functional neuroimaging is clearly very wide. Variations in the cerebral division of labor, both between subjects and over the course of time within a single subject, can be studied noninvasively with a hitherto unparalleled combination of temporal and spatial resolution. However, the small size of the signal changes results in vulnerability to misregistration artifact, and good reregistration software is essential. Vast quantities of image data can be generated rapidly using echo planar imaging methods (of the order of two gigabytes per day) so that fast-throughput computing facilities and major archiving capabilities are needed.

Be this as it may, a new era in human brain mapping is beginning. Research into the numerous areas of neuroscience and neurology will be accelerated by the relative ease, noninvasiveness, and good spatial and temporal resolution of these techniques.

1 INTRODUCTION

Functional neuroimaging with MRI (fMRI) may open up enormous possibilities for the study of human brain function in health and disease.^{1,2} It offers the combination of being noninvasive with the potential for high spatial and moderate temporal resolution.

Most functional MRI studies involve the acquisition of a series of images over time while the subject performs a task or experiences a stimulus. Images acquired with the subject in different states are then compared in order to detect signal changes associated with brain activation. The origin of such changes is widely thought to be associated with a localized hemodynamic response to increased neuronal activity. This response is thought to produce signal changes by two principal mechanisms: (a) changes in blood oxygenation state resulting in susceptibility mediated signal changes [the blood oxygen level dependent (BOLD) effect];³ and (b) signal changes associated with increased blood throughput.⁴ The signal changes attributed to these effects range from 1–2% up to 20–30%, depending on the MRI technique employed and the strength of the B_0 field.^{5,6}

Thus the task in functional MRI studies is to detect very small localized signal changes in a series of images of nominally the same anatomical structures. A key feature in this endeavor is the suppression of the wealth of anatomical detail that has hitherto been the hallmark of MRI in order to reveal functionally mediated signal variations. This change of emphasis has introduced a class of artifacts that are quite distinct from the imperfections usually seen on conventional *in vivo* magnetic resonance (MR) images.

This article is concerned with the artifacts that may occur in fMRI studies including ways in which they may be identified or reduced.

2 RECOGNITION OF ACTIVATION-INDUCED SIGNAL CHANGES

Detection of activation-induced signal changes generally relies on correlating changes in the signals from individual

image pixels or groups of pixels with the temporal structure of the activation protocol under study. The basic methodology employed owes much to studies of brain activity using positron emission tomography (PET),⁷ a technique with which functional MRI shows some similarities as well as some essential differences.

The majority of PET activation studies rely on detecting blood flow changes made visible by the injection of radioactive water. The data obtained typically display both a low effect-to-noise ratio and a large effect-to-resting-signal ratio. Thus the methodology employed is designed to detect a small coherent signal that may be buried deep in random noise. Statistical methods and spatial averaging are employed to discriminate against the noise,⁸ and signals that correlate with the activation protocol are taken to reflect activation-induced physiological changes.

In contrast, functional MRI is characterized by a small effect-to-resting-signal ratio with a high overall signal-to-noise ratio. Thus, although it is necessary to distinguish the desired effect from random noise, for which statistical methods akin to those employed in PET may be appropriate,^{9,10} it is also essential to differentiate signals induced by activation from all other sources of change in the resting anatomical signal. This latter task requires a different approach because the competing signal changes may also be temporally coherent with the activation paradigm. In addition, the resting signals also have pronounced spatial structure, so that spatial averaging (smoothing) may not preferentially reduce them as would be the case for random noise.

Coherent signal changes that may confound functional MRI studies can arise from a variety of sources. Both respiration and cardiac pulsations can cause signal changes in brain images.¹¹ Changes in the subject's state of arousal during activation studies thus may lead to signal changes that correlate with the task protocol. Large effects may be produced simply by changes in the subject's position during the course of a study. The structural content of MR images may result in steep intensity gradients at interfaces between tissues, so that a slight head movement between the baseline and the activated images may result in a substantial signal variation. If subject motion is correlated with the task paradigm, the signal change may become task locked. As a result, it is insufficient to rely solely on coherence with the task under study as a *sine qua non* of a genuine activation.

Recognition of artifacts is hampered by the suppression of anatomical details which removes many of the signs that radiologists conventionally rely on to detect them. Processing procedures that remove these landmarks may lead to confusion. For example, the discovery that detected signals are actually from the scalp or ventricles provides an obvious indication that something is amiss. It is important not simply to disregard these contributions to the overall activation map, but to recognize that whatever mechanism has produced them may also be contributing to less obviously erroneous signals.

Even when activation signals are apparently appropriately located, detailed study of the local anatomy is often revealing. For example, direct visualization of the local cortical structure can be invaluable for checking if 'cortical activation' signals cross tissue boundaries or do not in fact follow the line of the cortex at all. Figure 1 illustrates this for a hemifield visual stimulation experiment designed to detect susceptibility changes associated with the BOLD effect. Long echo time field

Figure 1 A visual stimulation study in which (a) an oblique transverse slice was repeatedly imaged with a field echo sequence (TR 150, TE 100, flip angle 65° , 18 cm FOV, 64×256 matrix) while the subject experienced periods of hemifield visual stimulation and darkness. (b) A difference image reveals apparent activation in only one hemisphere as expected. However, (c) use of a double inversion recovery sequence (TR 6080, TI_A 2600, TI_B 245, TE 16) to image selectively the cortex at the same resolution reveals that the “activation” signals in (b) follow the outline of the brain as visualised in (a) rather than the more complex cortical structure (c)

echo images acquired during the activation study [Figure 1(a)] do not provide clear differentiation of the cortex, so that the difference image (illumination of half the visual field minus darkness) appears to show a plausible activation signal in one occipital cortex [Figure 1(b)]. However, acquisition of images at the same resolution, but designed to display the cortex alone [Figure 1(c)], reveals that the ‘active’ region follows the outline of the brain and not the highly convoluted cortex. The difference image shown in Figure 1(b) is thus most unlikely to represent cortical activation, and further analysis showed it to be artifactual.

The process of recognizing genuine evidence for activation and rejecting other signal changes is still evolving. A cautious approach is indicated at present in which potential sources of error are identified and their effects at least quantified if they cannot be reduced or eliminated.

3 THE PROBLEM OF SUBJECT MOTION

Subject motion affects most MRI techniques to a greater or lesser extent. In most cases problems arise because of changes in subject position during the acquisition of image data. This may lead to gross motion artifacts or simply to an apparent reduction in the signal-to-noise ratio (see also *Whole Body Magnetic Resonance Artifacts*). Many techniques have been developed to minimize these effects, and some are now being applied to improve the quality of the individual images obtained in functional MRI studies.¹² The long TE field echo sequences used to detect BOLD changes are particularly vulnerable to instabilities of various kinds. Fast imaging techniques such as EPI are, in general, less vulnerable to image artifacts produced by motion of the subject during the scan.

Another kind of motion artifact is of particular importance in functional MRI. If the subject changes position between scans the anatomical content will change from one image to the next. This may result in artifactual signal changes even though the individual images are themselves relatively free from motion artifacts. It has been shown that subjects generally move to some degree during functional MRI studies and that this motion frequently has components that are correlated with the stimulus protocol.¹³ The result of such stimulus-correlated displacement is that the intensity in some pixels varies synchronously with the stimulus. Analyses designed to detect correlated signal changes extract these motion-induced effects along with any genuine activation effects.

A simple calculation illustrates the magnitude of the likely effects of changes in position. The signal intensity change ΔI caused by a small spatial displacement Δx in a region of an image where there is a pixel intensity gradient (dI/dx) is approximately

$$\Delta I \simeq \frac{dI}{dx} \Delta x \quad (1)$$

If the intensity difference between adjacent pixels is 20% and the subject has moved by 1/10 of a pixel, a signal change of 2% will result. This is the same magnitude as the expected signal change from brain activation, so that clearly only a much smaller shift could be tolerated without some form of correction being necessary. With typical imaging parameters (16–22 cm field of view, 64–128 phase encode steps), 1/10

pixel represents about $300\ \mu\text{m}$ or less. The restraint necessary to prevent motions of this size cannot be reliably achieved by noninvasive head-holding techniques.

4 IMAGE REGISTRATION

Fortunately, the wealth of structural (anatomical) information contained in MR images allows subject movements to be detected retrospectively and corrected. Image registration algorithms that can match MR images to a tiny fraction of a pixel are now available. Hitherto, most techniques have been designed for cross-modality image matching [MRI to computerized tomography (CT), PET to MRI, etc.],^{14,15} and frequently operator intervention has been required to select landmarks. However, Woods et al.^{16,17} have developed a simple, fully automatic procedure that can be used for intramodality matching, and their approach is now being refined specifically for MRI to MRI registration.

5 EVIDENCE FOR STIMULUS CORRELATED MOTION

Changes in subject position during brain activation studies may result in gross misregistration artifacts which can easily be recognized and may have little to do with the task under study. However, smaller more subtle movements are commonplace and their effects may be more difficult to recognize by image inspection alone.

The nature of subject motion during functional MRI examinations has been studied for both motor and visual activation paradigms.¹³ In these studies subjects were imaged using long *TE* rapid gradient echo sequences with a surface coil for signal reception. Repeated single-slice images of appropriate anatomical regions were acquired at a rate of one every 20 s. The stimulus condition was changed every five images. For the motor studies, the subjects performed finger to thumb touching continuously with one hand for the duration of five images and then changed hands for the next five images, and so on. At the end of the experiment all the images acquired with the left hand exercising were subtracted from all those with the right hand exercising and the results summed to form a cumulative difference image.

Figure 2 shows an example of the results obtained. The anatomical slice which was acquired in the coronal plane is shown in Figure 2(a) and the cumulative difference image is shown in Figure 2(b). The highlighted region in Figure 2(b) (arrow) shows where there was a localized signal change that correlated with the stimulus protocol; it increased when the right hand was active and fell when the left hand was active. The 'active' region is in an appropriate cortical location for the task being performed.

To examine the subject's motion during the study, an image registration technique¹⁶ was used to find the rigid body translations and rotations that were required to match the head position in each of the images obtained with that in a single base image. This resulted in the time series data shown in Figure 2(d). The top graph shows left-right shifts from image to image, the middle graph shows head-foot displacements, and the bottom graph shows in-plane rotations of the head.

Figure 2

Figure 2 (a) Anatomical image of the coronal slice chosen for a motor stimulation study. (b) The cumulative difference image, right hand action minus left hand action, reveals a focal high signal region in an appropriate anatomical location (arrow). However, (c) a strikingly similar pattern of focal signal change can be demonstrated to have been produced purely as a result of small changes in position of the subject during the study. (d) The position changes, as determined by an image registration technique, are plotted against image number (time). They reveal that small displacements tend to occur as the hand being exercised is changed (i.e. at multiples of five images). (e) A power spectral analysis of the movement time series in (d) reveals dominant peaks associated with the periodicity of the stimulus protocol

The magnitude of these displacements was less than 0.5 mm for translations and 0.3° for rotation.

Although the motion is small, there is evidence that the positional changes occur in concert with the task [Figure 2(d) note the left–right shifts at images 20,25,30,35]. To investigate this more systematically a power spectrum analysis was performed [Figure 2(e)],¹⁸ to reveal the dominant periodic components of the motion. In this analysis the unit of frequency was normalized so that unity corresponds to one motion cycle per stimulus cycle of 10 images. There is a particularly pronounced peak at 1 for the in-plane rotation, indicating that the subject had a tendency to nod their head from side to side in time with each change of hand. The peak at 2 in the left–right displacement spectrum shows that the subject was moving in a way that correlated with changes of hand, irrespective of which hand was being exercised.

To investigate the effect of the stimulus-correlated motion on individual pixel intensities in the difference image [Figure 2(b)], a synthetic data set was created. This was done by taking a single base image from the original functional series, replicating it, and then using the data obtained by coregistration to reposition the replicated images to match the position of each of the other images in the series. The resulting set of images matched the original experimental data by retaining the subject's anatomy and history of their motion, but specifically excluded other sources of signal change such as changes in blood flow or oxygenation state. The calculated cumulative difference image from the synthetic data set is shown in Figure 2(c) and replicates the highlighted region in Figure 2(b) that appeared to be due to brain activation.

Figure 2 thus illustrates that subject motion can correlate with the stimulus and cause signal changes that may easily be mistaken for evidence of brain activation. Similar analyses of four motor stimulation studies and four hemifield visual stimulation studies showed that stimulus-correlated motion was present in each case.¹³

6 CORRECTION OF MISREGISTRATION ARTIFACTS

The presence of signals that arise from changes in subject position during the course of a functional MRI study may not in itself be a problem, provided that the artifactual contribution can be recognized and dealt with in an appropriate manner.

Estimating the maximum displacement that may have occurred allows the magnitude of potential displacement artifacts to be quantified. Using the study shown in Figure 2 as an example, if the subject was known to have moved by less than Δx of a pixel from left to right, Δy from head to foot and to have tilted the head by less than $\Delta\theta$ radians in plane about a point (x_0, y_0) , then the maximum displacement-induced signal (ΔI) for a pixel at (x, y) can be estimated as:

$$\Delta I(x, y) = \sqrt{\left[\left[\frac{\partial I(x, y)}{\partial x} \Delta x \right]^2 + \left[\frac{\partial I(x, y)}{\partial y} \Delta y \right]^2 + \left[\left\{ -(y - y_0) \frac{\partial I(x, y)}{\partial x} + (x - x_0) \frac{\partial I(x, y)}{\partial y} \right\} \Delta\theta \right]^2 } \quad (2)$$

Figure 3 Vulnerability maps produced from Figure 2(a) which reveal the spatial distribution of all potential signal changes that could occur as a result of displacements of $\Delta x = \Delta y = 1/10$ pixel and $\Delta\theta = 0.02$ rad (a) and $\Delta x = \Delta y = 0$ and $\Delta\theta = 0.02$ rad (b)

Applying this formula to the image shown in Figure 2(a) with $\Delta x = \Delta y = 1/10$ pixel and $\Delta\theta = 0.002$ rad, and dividing ΔI by the resting pixel intensity, results in the image shown in Figure 3(a). Note that most of the cortex is vulnerable to motion-induced changes, with typical signal changes of 10–20%, even for the small displacements considered. The image shown in Figure 3(a), which we refer to as a ‘vulnerability map’, indicates the potential combined effect of all possible movements up to the chosen maximum displacement in x , y , and θ . Figure 3(b) shows another vulnerability map, but this time calculated with $\Delta x = \Delta y = 0$ so that it shows the distribution of signal change induced by pure rotations of the head. Note that the most prominent features are the same as those that are highlighted in Figure 2(b) and (c).

Vulnerability maps may be used as a thresholding device to subtract out potential motion effects. A signal change in a given pixel that was larger than the vulnerability for that pixel could then confidently be assigned to a cause other than motion. This approach is rather crude since, as can be seen from Figure 3, even modest displacements would lead to threshold criteria that would be unlikely to be exceeded by the expected genuine activation signals. A more rigorous approach is to quantify the exact displacements and correct for them, leaving a data set that can more confidently be analysed for evidence of genuine brain activation.

The image registration techniques already described provide a means of doing this; however, special care is required to ensure that the process of registration does not itself introduce artifacts. Since subpixel displacements are required, it is necessary to interpolate the image data to generate new interstitial pixel values.

6.1 Image Interpolation

Image matching is frequently performed using linear interpolation¹⁹ (see, for example, Woods et al.¹⁶). The effect that this has on MRI data can be determined with a simple experiment. An MR image, for example the T_1 -weighted image shown in Figure 4(a), is rotated using a computer, and new interpolated pixel values calculated to produce the image shown in Figure 4(b). The rotated image is then rotated back to its original orientation and the difference between the

original image and the doubly interpolated image is calculated. Figure 4(c) shows the result for linear interpolation. Substantial intensity errors have been introduced because the interpolation function does not match the structure of the image data.

Much more faithful interpolation can be achieved by making use of the fact that MR data are strictly band limited and, therefore, their in-plane point spread function is the sinc function.²⁰ Using sinc interpolation²¹ to rotate the images shown in Figures 4(a) and (b) produces much smaller differences [Figure 4(d)], with the maximum error now being less than 1% of the maximum signal.

6.2 In-Plane Registration

Sinc interpolation can form the basis of an in-plane misregistration correction scheme in which images are positionally matched with subvoxel precision and then compared in order

Figure 4 Displacement of image data by a fraction of a pixel requires image interpolation, which may introduce errors. These errors can be detected (a) by rotating a sample image by 10° to produce a second image (b) and then rotating (b) back to the original position. The final image, which has been interpolated twice, can then be subtracted from (a) to reveal any errors. Linear interpolation introduces substantial errors particularly at edges (c), whereas sinc interpolation is much more faithful to the original data structure (d)

to detect changes that are independent of the transformations employed.

A least-squares minimization procedure can be used to determine the required positional transformations. We employ the Levenberg–Marquart algorithm²² to minimize

$$\chi^2 = \frac{\sum}{\text{pixels}} \frac{(I_A - I_B)^2}{N} \quad (3)$$

where I_A and I_B are the intensities of corresponding pixels in the two images being matched, and N is the number of pixels included in the calculation of χ^2 . Minimization is achieved by rigid body rotation and translation of image A using sinc interpolation to generate new values for I_A .

Figure 5 illustrates the image registration procedure. A phantom [Figure 5(a)] was imaged twice with an in-plane displacement of approximately 2.5 pixels between the images. A difference image showing the effect of the displacement is shown in Figure 5(b). After χ^2 minimization, shifting one

image to match the other using sinc interpolation results in the difference image shown in Figure 5(c). The procedure has succeeded in reducing displacement-induced differences to the level of the background noise.

For in vivo studies, a further refinement is generally required because subject movement can introduce image differences caused by the differential displacement of soft tissues. It is therefore advisable to restrict the registration to those parts of the image containing the tissue of interest. This can readily be achieved by segmenting²³ one of the images.

6.3 Full Three-Dimensional Registration

The example illustrated in Figure 5 was restricted to in-plane displacements. In a living subject, we must expect full three-dimensional movement to occur, and thus single-slice data do not provide sufficient information. Conventional multislice techniques can nominally provide the required

Figure 5 Image registration allows subject displacement to be corrected. (a) A phantom imaged twice with a differential offset of 2.5 mm results in substantial misregistration signals when the two images are subtracted (b). (c) Using an automatic image registration algorithm to determine the spatial shift required and sinc interpolation to reposition one image at the location of the other, reduces differences to the level of the background noise

spatial coverage, but problems can arise with uncertainties of data content at the boundaries between slices. The fidelity with which multislice data can be interpolated in the through-slice direction depends on the details of the slice profile. An idealized profile with uniform sensitivity in the selected slice and zero outside is uninterpolable because each slice is represented by independent isolated data.

True three-dimensional volume data acquisitions (see also *Image Formation Methods*), in which phase encoding is used in the slice direction, are band limited in all directions and therefore can be faithfully interpolated using the sinc function. This type of acquisition is thus ideally suited to correction of arbitrary displacements. It has the drawback of being rather slower than the single-slice methods more commonly employed in functional MRI.

Figure 6 illustrates a motor stimulation study designed to detect changes in blood flow in draining veins, using three-dimensional acquisitions to image 40 slices. The subject performed hand exercises with one hand for the duration of a scan, changed hands for the next scan, and so on, for a total of six scans. Figure 6(a) shows one slice from one of the 40 slice sets. A cumulative difference image of the same slice [Figure 6(b)] shows obvious misregistration effects. In Figure 6(c) the images were registered before subtraction. Gross difference signals have now been eliminated from the brain, but some vessels can still be seen (arrow) as well as the scalp. Segmenting the image so that only the brain was used to calculate the transformations required for positional matching, but then transforming the original complete images, results in precise cancellation of signals from the brain and cerebral

Figure 6 A motor stimulation study in which each hand was exercised in turn as images were acquired repeatedly using an inflow sensitive 3D sequence (TR 40, TE 8, flip angle 20° , 192×256 matrix, 21 cm FOV, 40 slices of 1 mm) and a surface coil placed adjacent to the dominant hemisphere of the brain. (a) A single slice from the series and (b) cumulative difference image (right hand activation minus left hand activation). In (c) the images have been registered before subtraction and some vessels can still be seen (arrows) as well as the scalp. (d) Segmenting the image so that only the brain is used for detecting how the subject moved, but retaining all the information in the positionally matched images results in complete cancellation of brain and cortical vessel signals but leaves larger residual signals from the scalp

vessels but leaves residual signals in the scalp [Figure 6(d)]. This indicates that the relative positions of the brain and scalp have altered. However, although a task was being performed, no significant signal changes were detected in the brain or its draining vessels when these were precisely matched for position.

7 CONCLUSION

Functional neuroimaging using MRI is a new and challenging area of research. The detection of signal changes that correlate with the applied stimulus protocol is not in itself sufficient evidence for localized brain activation as there are other sources of such signals. Most notably, subject movement during the course of an examination can result in task locked signal changes that may not be discriminated against by correlation and statistical analyses. Single-slice studies are particularly vulnerable because of the lack of information about tissues adjacent to the slice, which makes it difficult to detect the effects of through-slice movement. Image registration provides a means of correcting for the effect of interimage displacements, but great care is required to ensure that the correction procedure itself does not introduce spurious results.

Hemodynamic Changes Owing to Sensory Activation of the Brain Monitored by Echo-Planar Imaging

Peter A. Bandettini, Jeffrey R. Binder, Edgar E. DeYoe, and James S. Hyde

Medical College of Wisconsin, Milwaukee, WI, USA

1 INTRODUCTION

In recent years, it has been demonstrated that MRI is capable of detecting changes in cerebral blood volume,¹ flow,² and oxygenation,^{2–5} that accompany an increase in neuronal activity. MRI methods that observe these activation-induced changes have been termed functional MRI (fMRI).

The most widely used fMRI method for the noninvasive mapping of human brain activity is based on blood oxygenation level dependent (BOLD) contrast.⁶ A localized signal increase in activated cortical regions is generally observed using a time-course collection of T_2^* -weighted images. A working model of this phenomenon is that an increase in neuronal activity causes local vasodilatation, which in turn causes blood flow to increase in such a manner that the amount of paramagnetic deoxyhemoglobin in the local vasculature is reduced. This reduction causes an increase in spin coherence and, therefore, an increase in signal when using T_2 - and T_2^* -weighted pulse sequences.

Support for the hypothesized BOLD contrast mechanism, as it relates to fMRI, comes from several studies. Local cerebral blood oxygenation has been observed to increase with neuronal activity.^{7–10} Brain tissue T_2 , T_2^* , and T_2' have been shown to be decreased and increased by cerebral blood oxygenation decreases and increases, respectively.^{6,11–15} In addition, brain activation has been shown to increase T_2 , T_2^* , and T_2' ,^{16–20} in proportions that show general agreement with mathematical simulations based on simplified models of the cerebral vasculature.^{21,22}

The applicability of fMRI depends on the degree to which the induced signal enhancement magnitude, location, and timing can be correlated with underlying neuronal activation. The signal enhancement magnitude is not only affected by MRI parameters, but is also dependent on hemodynamic factors (i.e. blood volume, oxygenation, vessel orientation, and radii), which vary significantly from voxel to voxel. Correlation between BOLD signal enhancement magnitude and cerebral blood flow has, nevertheless, been observed. Visual cortex activation studies have shown that BOLD signal enhancement has essentially the same flicker frequency dependency² as that of cerebral blood flow changes observed using positron emission tomography (PET).²³

The fMRI signal enhancement location and distribution is also an issue. The upper limit of spatial resolution of fMRI may be influenced by the degree to which an activation-induced modulation of the velocity or oxygenation of rapidly inflowing spins or large collecting veins may contribute to the signal change. Generally, the larger the collecting vessel, the more spatially removed the signal change is from the area of neuronal activation. Such vessel size weighting might depend strongly on the pulse sequence, field strength, and resolution used.^{16–26} Nevertheless, studies have shown that fMRI can reveal activity localized to patches of cortex smaller than 1.5 mm.²⁷

The temporal resolution of fMRI depends on the latency and consistency of the activation-induced signal change. Rise latency of 8–9 s from stimulus onset to maximal signal change and a fall latency of 9–10 s from stimulus cessation to baseline signal have been reported.^{2,28,29} The hemodynamic response time sets upper limits on the functional temporal resolution. A significant increase from baseline is generally observed to take place within 2–3 s after stimulus onset.^{2,28,29} Activation durations of less than 1 s are detectable^{30,31} and relative differences (in the rise time from adjacent regions or from different experiments) in the onset of signal enhancement may be discriminated to within a second.³²

Platforms on which fMRI are performed vary considerably. Primary differences are in field strength, pulse sequence, gradient and radiofrequency coil hardware, and postprocessing methods. The many trade-offs that exist between platform types have not been completely characterized, but it is clear that fMRI based on BOLD contrast benefits from high field strength, high system stability, high signal-to-noise ratio (SNR), and minimal pulsatile motion sensitivity. From reported results, it appears that these criteria are most readily met using echo planar imaging. Nevertheless, other techniques may be suitable. Initial successes in the performance of fMRI using BOLD contrast were published by groups using either EPI at 1.5 T,^{2,3} and 4 T,¹⁶ or fast multishot gradient-recalled imaging techniques at 4 T,⁴ and at 2 T.⁵ Results have since been reported using fast multishot gradient-recalled imaging techniques at 1.5 T.^{33–35} Pulsatile brain, cerebrospinal fluid, and blood motion apparently cause nonrepeatable ghosting patterns in sequential images obtained by conventional multishot techniques,^{36,37} thus adding significantly to the image signal variation in time. Multishot spiral-scan techniques have lower sensitivity to these contaminating pulsatile effects,^{36,37} and have been used successfully to perform high resolution fMRI at 1.5 T.²⁷

The use of a time course of images in conjunction with control over activation timing allows for the application of postprocessing methods which include the use of z maps,³⁸ and other statistical techniques.³⁵ In addition, other methods, including Fourier analysis,³⁹ temporal cross correlation,³⁹ and time–frequency analysis⁴⁰ have been successfully applied. While significant signal changes are easily observed using the most conservative statistical tests, a standardized method by which functional images are created has not been established. Using EPI, studies of the fluctuations in the susceptibility-weighted signal from a quiescent brain have been carried out,⁴¹ not only to determine the nature of the noise for application to statistical tests, but also to obtain potentially useful physiological information, and to determine the actual relationship between functional contrast to noise and field strength.⁴²

Because of the ease of use and accessibility of fMRI, many areas of the brain and many different tasks have already been studied. Studies that have been carried out include those of primary cortical regions including visual cortex,^{2,4,5,16,29,35,43} motor cortex,^{2,3,26,33,34,39,44–46} and auditory cortex.⁴⁷ Studies of higher cognitive function, including word generation,^{48,49} higher visual processing,^{35,43} visual recall,⁵⁰ complex motor control,⁴⁶ and single word semantic processing,⁵¹ have also been performed.

In this article, applications of fMRI to the mapping of cortex activated by sensory stimulation are summarized using time-course collection of gradient-recalled echo planar images at 1.5 T,^{3,39} and temporal cross correlation postprocessing techniques.³⁹ Specifically, auditory cortex regions were differentially activated by noise and speech sounds, and visual cortex regions were selectively activated by visual stimuli of different eccentricity.

2 POSTPROCESSING METHODOLOGY

Stimuli are presented in a repetitive on/off fashion for several cycles throughout each time course. Foci of brain activation are identified by cross correlation of the time course of each voxel with a reference vector resembling the expected activation-induced response.³⁹ In general, a reference vector may be obtained by: (a) choosing the voxel containing what appears to be the 'best' temporal response; (b) averaging, in time, the activation cycles in a 'best temporal response' voxel and then duplicating the time-averaged cycle for the length of the time course; (c) averaging in space several of the 'best temporal response' voxels; (d) synthesizing a reference vector; or (e) choosing a vector obtained from principal component analysis of the time course. Pixels having a temporal correlation coefficient below a given threshold (typically 0.4–0.6) are removed. After thresholding, the vector product of the reference vector with each of the surviving time courses is calculated to yield an index of change in the signal magnitude. These 'activation' images are then colorized and superimposed on high resolution anatomical scans of the same slice obtained in the same imaging session.

3 PULSE SEQUENCE AND HARDWARE

All studies presented in this article were performed using single-shot 64×64 gradient-recalled EPI ($TE = 40$ ms) on a clinical 1.5-T GE Signa scanner. To perform EPI without additional stress to the standard gradient amplifiers, we used an insertable balanced torque three-axis head gradient coil designed for rapid gradient switching.⁵² To obtain high-quality images throughout the entire brain volume, a shielded quadrature elliptical endcapped transmit/receive birdcage radio-frequency coil was used.⁵³ Typically, single- or multi-slice time-course series of 64–1024 images were obtained with a TR of 0.5–3 s, flip angle of 65–90°, field of view (FOV) of 24 cm, and slice thickness of 4–10 mm.

4 AUDITORY STIMULI

This study⁴⁷ presents findings using fMRI of brain regions involved in auditory speech perception. Specifically, regions activated by speech sounds (words and pseudowords) and non-speech sounds (noise) were compared.

Five right-handed subjects were tested. Symmetric lateral sagittal slices (slice thickness 10 mm) of the left and right hemispheres were obtained, centered at positions 8 mm medial to the most lateral point of the temporal lobe on each side. In each time-course series, 64 sequential images were collected ($TR = 3$ s), during which activation alternated with baseline every 9 s (6 images per cycle, 18 s per cycle, 10 cycles). During baseline periods, subjects heard only the ambient scanner noise. During activation periods, prepared digitized auditory stimuli were delivered to the subject via air conduction through a semi-rigid 1-cm-bore plastic tube. The tube conducted the sound stimulus approximately 20 feet (6 m) from control room wall to the subject, at which point a Y-connector split the tube for binaural stimulation through a tightly fitting headset with occlusive earplugs to reduce scanner noise exposure.

Subjects passively listened to stimuli; no response was required. Stimuli differed in both semantic and acoustic (frequency modulation) content. White noise presentation was compared to presentation of nouns (e.g. 'barn'), and pseudowords (e.g. 'narb') with stimuli matched for duration, presentation rate, average sound pressure level, and spectral range. All voxels having a temporal correlation coefficient to a sinusoidal reference vector below 0.5 were removed. The activation images were superimposed on high resolution scans of the same slices.

Figure 1 illustrates typical results from two of the subjects studied with white noise, pseudowords, and words, respectively. In these and all other subjects studied, the area activated by white noise was considerably smaller than that activated by speech sounds, and was restricted to the dorsal aspect of the superior temporal gyrus. In most instances, this region coincided with or included the transverse temporal (Heschl's) gyrus. Presentation of speech sounds activated a larger region, including more anterior and posterior areas of the dorsal superior temporal gyrus, as well as cortex in or near the superior temporal sulcus bilaterally.

Both words and pseudowords differed significantly from noise bilaterally, while no significant differences were seen between word and pseudoword conditions. Activity occurred symmetrically in the left and right temporal lobes. Unlike white noise, therefore, processing of speech sounds appears to elicit extensive participation of auditory association areas, even when the subject is not engaged in any 'active' task.

5 VISUAL STIMULI

Much of the utility of fMRI depends on its ability to depict spatial patterns of neural activity. To test this capacity in the visual system, fMRI was used for retinotopic mapping of primary visual cortex activation.⁴³

Dynamic, computer graphics-based visual images were directly projected onto the subjects' retinæ. The image generator was a modified Sharp XG2000U video projector driven by

Figure 1 Sagittal images of the left and right temporal lobes of two subjects. Demonstrated are regions activated during passive listening to (A) white noise, (B) pseudowords, and (C) words. The area activated by white noise was smaller than the area activated by either pseudowords or words. The area activated by pseudowords was generally the same size and shape as the area activated by words. (Reproduced with permission of the American Neurological Association, 1994)

Cambridge Instruments VSG video graphics board installed in a personal computer. The image plane was then viewed through a custom optical system that included a wide field, magnifying eyepiece, a 45° prism, and additional objective lenses for adjusting magnification and minimizing chromatic aberration. Two sets of imaging optics were combined to provide full binocular viewing.⁵⁴

To map the retinotopic organization of the visual cortex, three highly trained subjects viewed a small white fixation dot on a uniform black or gray field subtending 60° of visual angle. A black-and-white checkered annulus surrounding the fixation point was presented for 5 on/off cycles of 10 s on and 10 s off. Time-course series ($TR = 2$ s) of 100 images (slice thickness 8 mm) were used. When on, the checkered pattern was either counter-phase modulated or flickered at 6–8 Hz. Six successively larger annuli were tested. The width of each annulus as well as the check size were scaled in proportion to eccentricity. Only voxels having a correlation coefficient above 0.55 with respect to a chosen reference vector were used in the creation of functional images. All functional images were then superimposed on high resolution anatomical scans.

Figure 2 illustrates the relative sizes of the annuli and shows the corresponding brain activation images. In these experiments, the subject passively viewed the stimuli and was not required to respond to them. A small checkerboard annulus presented at the fixation point elicited activation in striate cor-

tex only at the occipital poles bilaterally. Annuli presented at increasing eccentricities activated successively more anterior regions of the calcarine sulcus. The most eccentric stimulus activated only the anterior calcarine cortex while sparing the occipital poles. Detailed examination of the sequence of activity foci in Figure 2, shows a progression that closely follows the folded cortical mantle within the calcarine sulcus. While such a precise progression is not always observed, these data do show that, under optimal conditions, a detailed mapping of the visual field representation is possible with fMRI. Resolution is not limited by the coarseness of the distribution of large blood vessels, even though such vessels may sometimes introduce artifacts.

6 CONCLUSIONS

MRI of human brain activation using BOLD contrast is a relatively new functional brain imaging method. Accompanying the novelty of the technique are many unknowns regarding the upper limits of spatial and temporal resolution as well as an unclear understanding of physiological and the biophysical mechanisms that regulate hemodynamic changes. In addition, the ways in which the hemodynamic changes affect the magnetic resonance signal are incompletely understood. Never-

Figure 2 Axial brain activation images created by passive viewing of visual stimuli with six different eccentricities while fixating at the center. The active foci traveled in an anterior direction along the calcarine fissure as the stimulus became more peripheral

theless, the applications described here and elsewhere empirically establish the utility of this approach.

These studies demonstrate observation by fMRI of human brain activation by sensory stimulation. Regions activated in temporal lobes by various speech and nonspeech auditory stimuli were observed. In addition, retinotopic organization of the primary visual cortex was observed using stimuli of varying visual field eccentricity. Additionally, in our laboratory, preliminary studies involving activation by tactile, aromatic, and taste stimuli are in progress.

fMRI is a technique that holds great promise in uncovering unique and useful information about brain function and physiology.

Postoperative Trauma Observed by MRI

David N. F. Harris

Royal Postgraduate Medical School, London, UK

1 INTRODUCTION

This article reviews the use of magnetic resonance imaging (MRI) in patients undergoing major cardiac and vascular surgery, with particular emphasis on the problems presented when imaging patients immediately after major surgery.

Up to 80% of patients develop neuropsychological defects following coronary artery bypass surgery (CABS), with 38% persisting at 1 year; this is thought to indicate permanent damage. Of CABS patients, 1–2% develop overt strokes with a higher incidence reported following valve surgery. The cause of the defects is not known, but cerebral emboli of both air and microaggregates, hypoperfusion, and release of cytokines from the trauma to blood cells by the cardiopulmonary bypass circuit have been implicated. It is not yet clear whether these defects are specifically related to cardiopulmonary bypass as the incidence of neuropsychological defects in noncardiac surgery varies widely in reported studies, and it is difficult to find a satisfactory control group for CABS patients.

Neuropsychological testing shows a high variability between patients, and performance on tests improves with practice (learning); different investigators also produce different results. Accuracy can be improved by using multiple tests and a battery of 10 is commonly used, but this reduces the sensitivity and makes assessment of subtle defects difficult. X-Ray computerized tomography (CAT) scanning is the most widely used test for detecting cerebral trauma; it shows abnormalities in patients who have suffered major neurological events, but often does not show such anomalies in patients with less severe deficits. The development of MRI offers the attractive possibility for sensitive and objective assessment of cerebral structure and function noninvasively.

2 CARDIAC SURGERY

2.1 Focal Defects

Schmidt et al.¹ investigated patients with 1.5 T MRI before and 1–3 weeks after CABS and showed an increase in focal defects—infarcts, lacunar lesions, and cortical atrophy. In 50 patients, Peden et al.² showed a high incidence of defects in the preoperative scans of CABS patients, with a significant increase in focal defects in 35% of patients 1 week after surgery; 20% of the defects persisted at 8 weeks. New defects were more common in those who had preoperative defects, and imaging defects were associated with neuropsychological deficits.

2.2 Swelling

To assess the incidence in the early postoperative phase we looked at six patients before, immediately after the end of surgery before going to Intensive Care, and 1 week after surgery.³ All patients showed marked cerebral edema on the immediate postoperative images, which returned to normal when imaged 1–3 weeks later (Figure 1). The cause of this swelling was not known, but it was suggested that it might reflect cerebral ischemia at the end of bypass as shown by jugular bulb desaturation.

2.3 High-energy Phosphates

To see if there was any evidence of ischemia, we studied eight patients with MR spectroscopy immediately after cardiac surgery, four with ¹H spectroscopy and four with ³¹P spectroscopy. There was no visible lactate either globally or regionally, the ratio of phosphocreatine to ATP was maintained, and there was no intracellular acidosis. However, phosphocreatine/inorganic phosphate was increased immediately after the operation, which suggests rebound replacement of energy stores following recovery from temporary cerebral ischemia during cardiopulmonary bypass: intraoperative studies would be needed to test this hypothesis further.⁴

3 MAJOR VASCULAR SURGERY

3.1 Aortic Aneurysm

It has been noted that many patients become confused 2–3 d after successful aortic aneurysm surgery. This was thought to be due to hypoxia over the first postoperative nights, but MR images in three patients who also exhibited confusion on neuropsychological testing showed cerebral swelling on the second and third postoperative day similar to that found after CABS, though to a smaller degree. One patient also showed cerebral swelling immediately after the operation which had returned to normal 14 h later.

3.2 Carotid Endarterectomy

We studied six patients immediately after carotid endarterectomy to see if cerebral edema was localized to the operative side. Four patients showed significant swelling, but no lateralizing signs were seen on FLAIR imaging.

With subtraction imaging, two patients with previous strokes showed deviation of the ventricles away from the infarct.

4 TECHNICAL REQUIREMENTS FOR EARLY POSTOPERATIVE SCANS

When imaging patients in the early postoperative period, great care must be taken to ensure the safety of the patients. As with any MR scan of the head, the patient must be still, with their head enclosed in a coil and inaccessible in the mag-

Figure 1 FLAIR (6000/160/2100) sequences before cardiac surgery (a) and 40 min after the end of cardiopulmonary bypass (b) in a 62-year-old patient. Sulci are clearly seen in (a) and are almost obliterated in (b)

net during the scan. Following any anesthetic there is a risk of nausea and vomiting, respiratory obstruction, or depression, as well as cardiovascular collapse. The incidence of complications depends on the length and severity of the operation, and patients are closely monitored in the recovery room by highly trained staff for between 30 min and 8 h following routine surgery so that such complications can be prevented or treated rapidly: this requires instant access to the patient. When discharged from the recovery area, the patient is considered to be safe under occasional and possibly unskilled observation.

Any of the above complications could be fatal if they occurred unnoticed during a scan when access is by no means instant. There is therefore a 'no-go' time after an operation, similar to the recovery time, during which it is difficult to examine patients safely with MR. After this time imaging can be performed, but it would be advisable to monitor the ECG and oxygen saturation (SaO_2) throughout the scan within 24 h of any operation; this is clearly an arbitrary limit. If the operation was major or prolonged, then measurement of blood pressure should be considered, and it should be possible to transfuse intravenous fluids at any desired rate. Usually this would require a suitably trained member of staff (anesthetist, critical care nurse) present in the magnet room.

If it is important to acquire MR scans within this time, it is safer to keep the patient under anesthesia throughout the scan and the transport to and from the MR unit; this requires the 'metal check' to be performed before the operation. Critically-ill patients can be transferred safely, but it requires a protocol with close attention to detail and safety. For the images immediately following CABS and aortic aneurysm surgery,

patients were required to be hemodynamically stable, with no likelihood of requiring cardiac pacing or massive transfusion.

The system described by Peden et al.² was used with minor modifications. All cables were enclosed together in tubing so that 'spaghetti knitting' and disconnections could be avoided. All intravenous extensions and infusions were attached and primed in the operating room to minimize hemodynamic changes, and anesthesia was maintained by infusion (fentanyl/propofol). Sufficient supplies of intravenous fluids (crystalloid, colloid, and blood) with a pressure infuser were available in the magnet room, and suitable vasoactive drugs were brought with the patient from the operating room (OR). The patient was transferred from the operating table to an MR compatible trolley and to the MR magnet couch using a flexible roller to ensure a controlled, smooth transfer; monitoring of ECG, invasive blood pressure, and oxygen saturation was interrupted for less than 10 s.

Intermittent positive pressure ventilation was provided using a jet ventilator⁵ with pressure sensed at the endotracheal tube to avoid compression losses in tidal volume over the 5 m from head to ventilator. Capnography was used to confirm the adequacy of ventilation and to warn of disconnections in the circuit as standard pressure sensing alarms do not work reliably over that distance. The patient's airway is not visible during the scan and disconnections are easily possible as the patient is moved into the magnet bore; if unnoticed this would be catastrophic. Two anesthesiologists remained in the magnet room throughout the procedure, continuing the same monitoring that had been provided in the operating room.

With this protocol it has been possible to investigate patients immediately following major cardiac and vascular sur-

gery while providing the same excellence of care that they had received in the operating room (and a similar system should be considered for subsequent studies). This has produced new and interesting information on postoperative cerebral edema.

5 SUMMARY

It is difficult to study cerebral function in the anesthetized, early postoperative, and critically ill patient; yet it is an area of great interest. MRI offers interesting information on cerebral function and structure, but these studies present difficult problems for patient safety. Monitoring should be available for ECG, invasive and noninvasive blood pressures, pulse oximetry, and capnography throughout the scans. Anesthesia/sedation must be maintained during transfer to and from the MR unit; this is usually best provided by intravenous infusion. Intermittent positive pressure ventilation must be available over a distance of 3–5 m, which requires care in the choice of ventilator. It is important to have extensions on all intravenous lines to enable fluids to be transfused and changed during a scan, and all lines and cables should be routed to avoid snagging during movement of the patient. As the patient's airway is hidden during scans, an anesthesiologically trained member of staff should be present throughout, and evacuation procedures established and practised.

With these protocols, MRI scanning can be offered safely to critically-ill patients, and has provided interesting new information on cerebral edema immediately after cardiopulmonary bypass surgery.

Abdominal MRA

Paolo Pavone, Andrea Laghi, Carlo Catalano, Valeria Panebianco, Francesco Fraioli, Isabella Baeli, and Roberto Passariello

University of Rome, 'La Sapienza', Italy

1 INTRODUCTION

The study of abdominal vessels by MRA is a new and interesting perspective available in a routine clinical examination. The main problem which has limited such applications of MRA is the sensitivity of this method to motion artifacts due to breathing, cardiac motion, peristalsis, and pulsatile blood flow. However, the improvement in technical equipment has made it possible to reduce these problems and to obtain an excellent evaluation of abdominal vessels.^{1,2}

To date, both the time-of-flight (TOF) and phase contrast (PC) techniques are used and each has its own advantages and disadvantages.³⁻⁵ The TOF method has a faster acquisition time and a higher signal-to-noise ratio (SNR), but it is very sensitive to saturation effects; as a consequence it is only possible to work with small volumes, particularly when a 3D technique is employed.⁶

Recently, a new method of study using a dynamic intravenous injection of gadolinium-DTPA in conjunction with a 3D TOF acquisition technique has been developed.⁷ The use of gadolinium shortens the blood relaxation time and overcomes in-flow saturation; hence it is possible to image arteries with a low flow velocity and large volumes. These vessels can therefore be imaged in any direction without saturation problem, i.e. using a coronal plane for the aorta and so reducing the acquisition time. However, the overlapping of venous structures occurs and presaturation pulses are not effective.

The phase contrast technique can be used over large fields of view because of its lack of sensitivity to the spin saturation effect. Other advantages are the complete cancellation of stationary tissues and the possibility of quantifying flow velocity. By comparison, PC techniques require longer acquisition times and are very sensitive to motion artifacts, especially if such motion is not constant during image acquisition.

In the evaluation of abdominal vessels, contrast-enhanced MRA is currently considered the only technique able to provide anatomical images of all major vessels, allowing an optimal image quality, with improved diagnosis.⁶ Using this technique, all the datasets needed can be acquired during a breath-hold, provided that enhanced gradient systems are available to reduce repetition and echo time dramatically.

This overcomes the old problem with the conventional TOF or PC methods in which long acquisition times and the complexity of flow effects resulted in a myriad of artifacts, rendering a considerable fraction of examinations unreadable.

Furthermore, arterial blood is clearly visualized because it contains the paramagnetic contrast agents. The presence of paramagnetic agents such as a gadolinium chelate rapidly reduces the T_1 relaxation time of blood from 1400 ms to 200–400 ms depending on the dose and the rate of injection.

Obviously the visualization of blood depends on the presence of contrast in the arterial system while the 3D imaging data are being collected; this makes the technique very sensitive to the timing of the intravenous contrast administration relative to data acquisition.⁷

Great efforts have been made in recent years to improve further the image quality of enhanced MRA. These have been aimed at the improvement of the pulse sequences on the one hand and the contrast agents used on the other.

Improvement of the pulse sequence for enhanced MRA must involve one single and important issue: minimizing dephasing phenomena, thus reducing the signal loss related to phase dispersion of flowing spins, mostly evident in stenotic (jet flow) and tortuous vessels (turbulent flow). These effects are, in fact, still evident even when enhanced techniques are used, despite the fact that these newer sequences visualize directly the effect of the contrast agent (T_1 shortening) rather than the flow phenomena. Reduction of phase dispersion is achieved by using either optimized gradient rephasing pulses or, in a more effective way, by reducing the echo time of the pulse sequence. With current commercial equipment, a minimum echo time of 1.5 ms can be used, and the improvement achieved in moving to this from the 3 ms available on older equipment is really dramatic, with more consistent evidence about small vessels and better definition of the true diameter of every vessel imaged by MRA. Moving to shorter echo time has only one important requisite: that the gradient characteristics of the equipment are optimized. Current equipment must have a gradient strength of at least 20 mT m⁻¹ and a rise time of 400–800 μ s.⁸ Specialized equipments for use in the cardiovascular system are being produced that have a gradient strength of 40 mT m⁻¹, although they are currently being offered only for research purposes.

Another way to improve the image quality in enhanced MRA is to use more effective contrast agents. Conventional gadolinium chelates have basic pharmacokinetics, with intravascular–extracellular diffusion. In practice, these agents pass rapidly through the capillary membrane and very rapidly (within 5 min) reach pseudoequilibrium between the vascular and the interstitial concentration. There are two ways to improve the characteristics of the contrast agent for enhanced MRA: by using a contrast agent with the same pharmacokinetic characteristics but having an increased relaxivity (the capacity to influence the local magnetism and, therefore, the T_1 relaxation time of blood), or by using contrast agents with prolonged blood half-life, having a lower capacity to diffuse through the capillary membrane.

The first approach is used with a new gadolinium chelate Gd-Bopta (Multihance, Bracco). This contrast agent was initially proposed only for hepatobiliary use, because of its consistent biliary excretion, but has now also been applied for general purposes, because of its good characteristics. In particular, in the vascular system, this contrast agent is able to provide a very high enhancement of the vascular structure because its relaxivity is almost twice as great as that of other gadolinium chelates in human plasma (R1 9.7 versus 4.9 for Gd-DTPA). Early studies have demonstrated that evaluation of abdominal vessels by enhanced MRA is improved by this contrast agent. The second approach is to use contrast agents that are not able to cross the capillary membrane rapidly. The first class of such contrast agents are the macromolecular com-

pounds, where a long molecular chain with large molecular weight is bonded to gadolinium. Schering has proposed a gadolinium chelate covalently bound to a polymer composed of polylysine (Gadomer 17). This compound has a molecular weight of 30–35 kDa, with high relaxivity, good acute tolerance, low viscosity, and low osmolality. In early studies, this contrast agent has been able to improve the enhancement of vessels and to provide prolonged evidence of the vascular system in enhanced MRA. The second class of contrast agent that is not able to cross the capillary membrane rapidly is represented by one single molecule: MS 325, first synthesized by EPIX and currently produced by Mallinckrodt. This contrast agent is rapidly bound to human serum albumin after being injected into the vascular system, with a strong but short-lasting link. In fact, after a few hours all the contrast agent injected is free from this link and is excreted through the kidneys. The result is that this agent provides a very high enhancement of the vascular system that is prolonged in time. The advantage of using intravascular agents is that the whole vascular system can be imaged more safely, with images being acquired in different anatomic areas, without the need for giving repeated injections of contrast agent at each anatomic level. In conclusion, there is no doubt that contrast-enhanced MRA is the technique of choice for abdominal MRA. Hardware improvements are to be expected and the use of newer contrast agents will definitely contribute to increasing the image quality and clinical value of this technique.

2 CLINICAL APPLICATIONS

2.1 Abdominal Aorta

The main clinical application of aortic MRA is the study of aortic aneurysms in terms of the extent and size of the pathology as well as the involvement of collateral vessels, identification of either an aortic stenosis or a thrombus in an atherosclerotic vessel and evaluation of either the patency or the complications of a graft.⁹

In the study of aortic aneurysms MRA is complementary to conventional spin echo images. In fact, a complete evaluation of the diameter of the lesion is possible only after a study performed using spin echo sequences. However, MRA has a major role in defining the size of the true lumen, in depicting the neck of the aneurysm, and a potential role in the quantification of the blood flow. Figure 1 illustrates the utility of MRA in the evaluation of an aortic aneurysm. By reconstructing the images with maximum intensity projection (MIP), it is possible to obtain a clear definition of the relationship between the aneurysm and the other vessels arising from the aorta. One study¹⁰ showed a sensitivity of 67% and a specificity of 96% for MRA in the identification of proximal stenosis of the renal artery involved by the aneurysm (Figure 2), and a sensitivity of 67% and a specificity of 100% for stenosis of the celiac trunk and of the superior mesenteric artery.

Enhanced MRA is particularly useful in the evaluation of abdominal aortic aneurysms. In fact, the presence of blood turbulence has limited to a large extent the use of nonenhanced techniques, with areas of flow void related to spin dephasing. With enhanced MRA all these problems are overcome, and the

use of a coronal acquisition makes it possible to image the whole aorta and ilio-femoral district in one single field of view (FOV of 50 cm can easily be used). The absence of excretion toxicity from gadolinium compounds also permits a complete study in patients with suspected renal arterial stenosis or involvement. Currently, noninvasive 3D imaging studies (either CT or MRI) are recommended for the evaluation of abdominal aortic aneurysms, avoiding the use of invasive catheter angiography. In particular, the aim is to determine the treatment that is to be performed in each patient; endovascular placement of aortic stent grafts can be developed as the treatment of abdominal aortic aneurysms, and all the data needed to evaluate if the graft can be placed can be collected.

A study has compared the results of MRA and CTA (CT X-ray angiography) for evaluating the information needed for graft placement.¹¹ Both techniques agreed with catheter angiography (as gold standard) in the measurement of the abdominal aorta at the level of its largest diameter and at the level of the renal artery ostium. Another measurement that was obtained consistently with good agreement with both methods was the definition of the distance between the renal arterial ostium and the origin of the aneurysm. For tube graft placement, a distal nonaneurysmatic segment of at least 15 mm is mandatory. This distance was also measured equally well by CTA and MRA (Figures 3 and 4).

Another important issue is the evaluation of accessory renal arteries. In initial studies, MRA had generally performed very poorly, with sensitivities lying between 28 and 92%. More recent studies have reported an accuracy of 100%. The importance of breath-hold MRA is shown in all these studies. In general, 12% of patients with abdominal aortic aneurysms present with accessory renal arteries, and information about them is crucial for proper treatment planning. CTA and MRA now also offer similar results in this field.

Other information that is provided by MRA concerns the patency of the mesenteric artery: in some cases the inferior mesenteric artery may be patent and this can cause revascularization of the aneurysmal lumen through reverse flow. The status of the iliac vessels has also to be evaluated. The possibility of stenosis has to be considered, since the endovascular stent graft is of fixed expanded diameter once introduced (18 F requires a minimum vessel diameter of 6 mm). Involvement of the iliac arteries through aneurysmal dilatation does not prevent the placement of a stent graft, but size and location should be considered carefully in deciding on the type of graft to be used and the best approach to its location.

Material arising from thromboses adhering to the walls can result in underestimation of aortic diameter and misinterpretation of the proximal extent of an abdominal aortic aneurysm. Evaluation of images acquired in the axial and coronal planes with gradient echo sequences straight after the MRA sequences (when contrast agent is still enhancing the vascular lumen) permits a detailed evaluation of the thrombus.

Some advantages for MRA do exist compared with CTA: the use of safer contrast agents, which can be used as well in patients with initial renal insufficiency; the use of nonionizing radiation; the possibility of acquiring images directly in the coronal plane, with a more consistent longitudinal (or *z* axis) resolution; and faster postprocessing analysis (as a 3D MRA dataset is composed of far fewer images than those provided by CTA). However, MRA also has some drawbacks, including

Figure 1 Abdominal aortic aneurysm; evaluation with the 3D TOF technique after gadolinium injection. (a) Single coronal slice depicting the true lumen of the aneurysm; the image also allows the thrombotic part to be recognized. (b) MIP reconstruction of the same aneurysm; good visualization of the abdominal aorta from the renal arteries to the iliac vessels is obtained. (c) Magnification of the iliac bifurcation with evidence of involvement of the right common iliac artery and a tight stenosis at the origin of the left common iliac artery

the usual contraindications for MR in general (such as implanted pacemakers). Further, inaccuracy in the detection of small accessory renal arteries must be considered, although this problem may be overcome by continuing technical improvements that allow imaging with better spatial resolution and visualization of very small vessels.

Another field of application for MRA is in the evaluation of leaks after the placement of endovascular stent grafts.¹² Follow-up of endovascular grafts is required in order to evalu-

ate the success of the treatment and the development of complications. In the early phase after placement of an endovascular graft, it is important to ensure that the procedure has led to technical success and that there is no leakage of blood between the graft and the native lumen of the aneurysm, which is better known as endoleak. The two major complications observed in the first series reported by Moore¹³ were stent fractures (23%) and endoleaks (44%); 23% of the endoleaks had spontaneous closure. Stent fractures have been corrected fol-

Figure 2 Volume-rendering reconstruction clearly visualizes the celiac trunk, mesenteric artery and both renal arteries in a patient with aneurysm

lowing a modification in the stent hook design by the manufacturer. However, the endoleaks remain a significant problem and may be associated with an increase in aneurysmal diameter at 1 year.¹⁴

In the long-term follow-up of aneurysms treated with a stent graft, it is necessary to monitor the caliber of the lumen of the aneurysm at regular intervals. In fact there have been several case reports of ruptured aneurysms after stent-graft repair. A noninvasive technique is required to monitor all these potential complications, and catheter angiography should be limited to the role of guidance of interventional procedures needed to correct such complications. Ultrasound may be able to provide consistent information with high accuracy in defining the presence of leaks or in evaluating the caliber and patency of the aorta and of the iliac vessels.¹⁵ The value of CT has also been advocated;¹⁶ with current helical acquisition it is possible to reconstruct angiographic projection images. CT is

considered to be the required investigation for the EUROSTAR registry.¹⁷

With MRA, both types of endoleak can be easily detected by the evaluation of areas of increased signal intensity detected after contrast agent injection. Moreover, 3D images provided by MRA are able to define both the patency and morphology of the stent graft and its relative position compared with the origin of the renal arteries.

2.2 Renal Arteries

Several types of examination have been used during the past few years for the evaluation of renovascular hypertension, but many have been abandoned because of their invasivity. Although digital subtraction angiography (DSA) and conventional angiography have become increasingly important because of the success of percutaneous procedures, they still remain too invasive as screening method procedures.

It is now possible to propose MRA of the renal arteries as an accurate, noninvasive diagnostic procedure in the evaluation of renal artery stenosis, especially of the ostium of the renal vessel.¹⁸ An example of MRA of the renal arteries is shown in Figure 5. Recent data show the high accuracy of MRA, which is similar in this case to conventional angiography in detecting both the normal and accessory renal arteries as well as the anomalous vessels. According to the literature, MRA has a sensitivity varying between 89% and 94% and a specificity of between 95% and 97%.^{19,20}

The evaluation of renal arteries has been performed principally with DSA, ultrasound, and conventional CT during the past few years.

Different etiologies are implicated in renovascular disease and, in most cases, the renal arteries are affected as part of the entire vascular system. Because of the continuous advances in percutaneous endoluminal therapies, the best possible imaging method is required in the detection of renovascular diseases.

According to the literature, MRA allows the visualization of all the main arteries as well as accessory arteries. In the detection of stenosis, the MRA sensitivity and specificity amounted

Figure 3 CT axial image with the aneurysm lumen surrounded by thrombotic material

Figure 4 Maximum intensity projections (MIP) show the extension of the aneurysm and the renal involvement

to 93% and 90%, respectively, with a negative predictive value of 96%.^{21,22}

In contrast to other noninvasive techniques such as scintigraphy or ultrasound, contrast-enhanced 3D MRA allows visualization of accessory renal arteries with a high degree of accuracy. The visualization of accessory arteries is especially important in the evaluation of renal transplant donors. Imaging must be completely accurate before surgical revascularization or nephrectomy in living-related renal donors can be contemplated.

As far as atherosclerotic lesions are concerned, the diagnostic performance of 3D MRA is still limited, particularly when all forms of stenosis are considered; in fact, as seen in the literature, there have been a considerable number of false-positive and false-negative findings.²³ Therefore, the gold standard diagnostic procedure for detecting arterial stenosis still remains angiography, though this is an invasive examination that exposes the patient to ionizing radiation as well as iodi-

nated contrast material, which may cause allergic reactions and/or nephrotoxicity. Therefore, according to the literature,²⁴ contrast-enhanced 3D MRA is, as yet, only a promising approach to obtaining contrast arteriography but is comparable to arteriography in the assessment of renal artery morphology and pathologic states. It does not involve the risk of arterial catheterization, ionizing radiation, or nephrotoxic contrast material.

2.3 MR Venography (MRV)

Studies of abdominal veins are an interesting application of MRA. It is possible to evaluate the normal and pathologic anatomy of the portal system, including the splenic vein, the superior mesenteric vein (SMV), and the eventual collateral vessels.²⁵ The relatively slow and homogeneous venous blood

Figure 5 Axial MIP reconstruction of renal arteries; good evaluation of the distal part of the vessels is also obtained

flow allows high-quality images to be obtained in almost all patients. The large FOV permits the imaging of the whole spleno-portal axis and the collateral vessels at the same time. This option is not available in any other imaging technique such as DSA, duplex scan, or color Doppler ultrasonography.

The main technical difficulties arising from respiratory and peristaltic motion, and to the different flow direction and velocity in abdominal vessels, have now been overcome by new image acquisition procedures. The breath-hold coronal TOF technique is the preferred method with which to image the abdominal veins. An image can be acquired in about 8 s and in a few minutes all the abdominal vessels can be displayed. It is, therefore, possible to obtain a selected evaluation of the portal vein or any of the other vessels by acquiring the images in the plane corresponding to the vessel to be studied. Because of saturation effects, all the vessels not in that plane will not be depicted.

To obtain a more selective evaluation of the venous system, it is possible to use more sophisticated techniques such as bolus tracking and selective presaturation. Those two options allow the clinician to define accurately the flow direction in a vessel and to distinguish a thrombus from flowing blood. Furthermore, they permit the selective suppression of the signal coming from specific arterial vessels or veins. After acquisition of the data, a postprocessing MIP technique can be used to reconstruct the images. Thus, it is possible to rotate the vessels and to show them on the monitor in the most useful projection and it is also possible to recognize strange anatomic variants in this way.

Portal hypertension represents one of the major fields of application of MR venography (MRV) in the abdomen (Figure 6). Because of the large FOV, MRV allows the whole spleno-portal axis and its collateral vessels to be shown at the same time in almost all patients. It is possible to evaluate the diameter of the portal vein and, with adequate techniques, to obtain quantitative information about the blood flow. Compared with color Doppler ultrasonography, which can actually be considered to be the method of choice for the screening and follow-up of patients with portal hypertension, MRV is not operator-dependent; it is not influenced by the presence of ascites, which is very common in these patients, or by colic

meteorism and patient habitus, all of which disturb a sonographic examination.

Another recent clinical indication for MRV is the evaluation of complex venous disease in cases of liver transplantation. MRV is very accurate and has a good correlation with DSA and duplex ultrasound. Moreover, MRV displays images in different orientations: thus the reconstructed images can be easily interpreted by the surgeon and complex structures can be demonstrated better than by any alternative imaging method.

Following liver transplantation, complications may arise as a result of anastomosis failure or stenosis. In this case the examination technique is ultrasonography, which has an important limitation in depicting the anastomosis. MRV can also show the condition through the paramagnetic effects of the material in the anastomosis, which creates a lack of signal. Additionally, anastomosis on the hepatic artery can be depicted by MRA in a high percentage of patients.

Finally, another recent field of application for MRV is the study of the patency of both surgical and percutaneous shunts of the ortho-systemic structure (TIPS). MRV makes it possible to obtain a noninvasive postsurgical follow-up. The anastomosis can be identified, flow direction established, and both size and patency of the shunts evaluated. After TIPS procedures the position of the stent can also be accurately determined.

There are a few pitfalls and limitations in the use of MRV in the portal system. At a venous confluence, such as the junction of superior mesenteric and splenic veins, a signal void may occur simulating a thrombus. In order not to misunderstand this artifact, gradient echo images can be acquired in different orientations through the questionable area. Changing the slice orientation can also be useful sometimes so as to

Figure 6 2D TOF MR venography. (a) MIP reconstruction shows the inferior vena cava (IVC) with the hepatic vessels and the portal vein. (b) Good evaluation of the portal vein and its bifurcation. The IVC and one hepatic vessel are also depicted

avoid the in-plane saturation effect. Usually, this is not as common for the portal system as it is for the aorta or the inferior vena cava, but a verticalization of the portal axis together with slow flow, as in a cirrhotic patient, may impair signal acquisition.

In conclusion, MRV of the portal system is extremely accurate and complete for the evaluation of these vessels. The large field of view, the insensitivity to patient habitus and the graphic presentation format make it very useful for preoperative assessment in patients with portal hypertension.

Assessment of Regional Blood Flow and Volume by Kinetic Analysis of Contrast-Dilution Curves

Johannes C. Böck and Roland Felix

Freie Universität Berlin, Germany

1 INTRODUCTION

The success of clinical magnetic resonance imaging (MRI) is based on its superb anatomic and contrast resolution, in particular in the central nervous system. However, MRI was initially unable to contribute to the field of perfusion imaging because of two factors: the lack of MRI contrast media and insufficient temporal resolution of the pulse sequences.

Contrast media are now available. The first agent in clinical use was gadolinium-DTPA, a well-tolerated ionic paramagnetic contrast agent developed by Schering AG, Berlin and first used in humans at our Institution in 1983.¹ After intravenous injection, gadolinium-DTPA is distributed in the extracellular space with the notable exception of the central nervous system, where the extravasation of gadolinium-DTPA into the interstitial space is effectively prevented by the intact blood/brain barrier. No such barrier prevents leakage of gadolinium-DTPA in the normal myocardium.

The limitation of temporal resolution has been overcome by the development of pulse sequences such as gradient echo and echo planar imaging. These pulse sequences allow for acquisition times ranging from 0.5–20 images per second, sufficient to follow the first passage of a contrast bolus through an organ.

In 1986, Haase et al.² published a report which pioneered contrast enhanced perfusion MRI. In an experimental model, they combined the intravenous bolus injection of the first available paramagnetic contrast agent, gadolinium-DTPA, and a new rapid image acquisition strategy 'fast low angle shot' (FLASH). When a series of images was acquired in the same slice position after contrast bolus injection ('FLASH MR movie') a reversible signal intensity decrease was observed in the brain which apparently coincided with the first pass of the contrast medium through the brain.

Unfortunately, the interpretation of the contrast kinetic is limited because of the physical properties of currently available contrast agents, which distribute either in the intravascular space (in the intact brain) or, in addition, in the interstitial space (in the myocardium but also in cerebral pathologies with disruption of the blood/brain barrier). From a rigorous mathematical standpoint only relative cerebral blood volume can be calculated on the basis of concentration–time curves measured in the brain³—cerebral blood flow can only be estimated.^{3,4} Since gadolinium-DTPA is not a strictly intravascular contrast medium in other organs than the brain, both blood flow and volume cannot be derived from gadolinium-DTPA kinetics measured in the myocardium and the kidneys.

By contrast, organ blood flow can be quantitatively assessed using diffusible contrast media such as deuterium oxide⁵ or H₂¹⁷O.⁶ However, these techniques will not be addressed in depth in this article since clinical experience is still lacking, probably because the methodology requires an injection either directly into the tissue or into the feeding artery. A less invasive approach, intravenous injection, would require the measurement of the concentration–time curve in the feeding artery and deconvolution of the arterial and tissue curves.⁷ Such techniques offer the same advantages as positron emission tomography in that blood flow can be measured in absolute terms (mL min⁻¹ per 100 g of tissue).

2 PRINCIPLES

Conventional contrast enhanced MRI using paramagnetic agents such as gadolinium-DTPA relies on dipole–dipole interactions between the nuclear spins of local protons and unpaired electrons of the contrast molecules. These interactions shorten the T_1 relaxation times and thereby increase signal intensity in the interstitial space *minutes* (the time required for contrast extravasation) after injection. If, however, the contrast is rapidly injected as a bolus, and if an appropriate (susceptibility-sensitive) pulse sequence is used, then a signal intensity *decrease* is observed within *seconds* after injection. The underlying mechanism is the compartmentalization of the contrast material in the vasculature (at least in the brain) with consecutively high contrast concentration gradients between the intravascular and interstitial compartments. (Positive) susceptibility is the property of paramagnetic substances to produce an intrinsic magnetic field when exposed to an extrinsic magnetic field. Because the magnetic susceptibility of gadolinium-DTPA is different to that of biological tissues, the contrast concentration gradients translate into regional (intravoxel) magnetic field gradients.

Intravoxel magnetic field inhomogeneity broadens the resonance frequency spectrum with subsequent dephasing and signal loss. Since gradient echo pulse sequences do not refocus static magnetic field inhomogeneities, signal intensity is directly affected by this process, in particular when the echo time is long (on the order of 20 ms). Spin echo pulse sequences do refocus *static* inhomogeneities and are therefore only sensitive to dephasing of mobile spins (diffusion of water molecules); again, the sensitivity increases with the echo time.

The signal intensity decrease is reversed as the contrast bolus passes the brain (first pass); however, a second (third, etc.) passage of the contrast (systemic contrast recirculation) is usually observed *before* the baseline signal intensity has been reached.

For further computations (e.g. blood volume), indicator dilution theory requires a concentration–time curve which can be computed for every voxel on the basis of the measured signal intensities by logarithmic transformation.⁸

$$c(t) = -\ln[S(t)/S(t_0)]/(k_2 TE) \quad (1)$$

(c = concentration, S = signal intensity, t = time, t_0 = time of injection, k_2 = constant depending on system and tissue properties, TE = echo time).

Figure 1 Sixty-one year old man with focal seizures of the right arm and speech arrest. Left parietal mass with homogeneous hyperperfusion pattern documented by MRI and confirmed by the radionuclide reference technique. Histology: meningiomatous and angiomatous meningioma. (a) T_2^* -weighted first-pass study (subtraction image); (b) radionuclide study (HMPAO-SPECT)

The postprocessing algorithm is based on the hypothesis that the area under the concentration–time curve recorded in every voxel reflects regional cerebral blood volume.⁹ This assumption is correct for the first pass of the contrast bolus and requires numerical elimination of recirculating contrast. This is achieved with sufficient accuracy by a nonlinear least-squares fit procedure using a γ -variate or some other algebraic function as a model for the cerebral contrast transit in the absence of systemic contrast recirculation. Finally, a parameter image is generated in which the brightness of each voxel reflects the area of the concentration–time curve and thus regional cerebral blood volume.

In the myocardium, the contrast extravasates into the interstitial space. This already occurs to a substantial degree during the first pass;¹⁰ the area under the concentration–time curve therefore does not correspond to a well-defined biologic compartment, but reflects the intravascular and a variable portion of the interstitial compartment. Myocardial blood volume can therefore not be derived from the concentration–time curve of small molecules¹¹ like gadolinium–DTPA. The use of a macromolecular agent with a molecular weight above 20 000 Da such as gadolinium–DTPA–polylysine¹² would be required for this purpose, but macromolecular agents are not yet available for clinical use.

As already mentioned, there is no rigorous theoretical concept for the construction of parameter images from concentration–time curves which reflect regional cerebral or myocardial blood flow. Some approaches are based on mean transit time concepts although the correct regional mean transit times cannot be determined using intravascular contrast agents.^{3,4} In fact, the mean transit time calculated from the tis-

sue concentration–time curve alone (without consideration of the arterial input function) overestimates the true organ mean transit time (which is on the order of only a few seconds in the brain) by more than 100%. Correction for the dispersion of the contrast bolus outside of the brain (finite injection duration, passage from the peripheral vein to the brain) would require numerical deconvolution of the tissue curves with the arterial input function. Although the arterial input function can be measured¹³ it is not the correct input function for every voxel. Finally, since the volume of distribution of gadolinium–DTPA-type contrast material is restricted, the inverse of the (correct) mean transit time would not represent blood flow in terms of [mL min^{-1} per 100 g tissue] but blood flow per unit blood volume [mL min^{-1} per ml blood]. Despite these limitations, some investigators have used transit time approaches with some success.^{14–17}

Another approach is to calculate a subtraction image where the image acquired at the time of maximum cerebral contrast concentration is subtracted from an image acquired before any contrast has reached the brain on a voxel-by-voxel basis [Figure 1(a)].¹⁸ The underlying theoretical concept is valid under certain experimental conditions¹⁹ and requires the consideration of the arterial input function. Fortunately, the arterial input function can be neglected as long as the image contains its own reference (e.g. the normal contralateral hemisphere), since the arterial input function is identical for all voxels under considerations in this concept. Subtraction images appear to reflect regional cerebral blood flow as assessed by an established radionuclide reference technique (HMPAO–SPECT) in the vast majority of patients with cerebral infarcts¹⁸ and in all patients with homogeneous

intracranial tumors [Figures 1(a) and (b)].²⁰ Discrepant results between the radionuclide method and first-pass subtraction images were found in inhomogeneous tumors (vital tumor/necrosis/edema). However, the discrepancy did not appear to result from the inability of MRI to depict adequately regional cerebral blood flow in these tumors but from the lower spatial resolution of SPECT (voxel volume = 1500 mm³) versus MRI (voxel volume = 50 mm³).

3 CEREBRAL PERFUSION IMAGING

Clinical experience with contrast enhanced MR perfusion imaging is steadily increasing. A number of recent reports focus on cerebral ischemia, intracranial tumors, and arteriovenous malformations.

In cerebral infarcts, regional cerebral blood flow is usually decreased but a hyperperfusion pattern is identified in some cases.^{18,21} While the prognostic significance of the hyperperfusion pattern in subacute infarcts has yet to be established, one might speculate that evidence of reperfusion indicates a better clinical outcome.

The grade of malignancy of intraaxial tumors appears to be correlated with the perfusion pattern. Low-grade astrocytomas are characterized by decreased blood volume when compared with contralateral gray matter. High-grade astrocytomas show either a homogeneous increase of blood volume or signs of marked inhomogeneity. These findings parallel—to a certain degree—the extent of the blood/brain barrier disruption as demonstrated by contrast enhancement on T_1 -weighted (or cranial computerized tomography—CCT) images. However, it is important to remember that the blood/brain barrier and regional cerebral perfusion are two distinct features which obey different underlying regulating and disturbing mechanisms.²²

Multiple biopsies of intraaxial tumors have shown that high-grade tumors are composed of tissues with different histological grading. It is obvious that biopsies should be obtained from the most malignant part of the tumor. These areas are often characterized by increased metabolism, increased tumor blood flow, and volume. Perfusion imaging should therefore be considered for optimal biopsy guiding.²³ The differentiation of radiation necrosis after therapy of high-grade intraaxial tumors from recurrent tumor is cumbersome because both present with mass effect, necrosis and blood/brain barrier disruption. However, initial clinical results indicate that blood volume is homogeneously decreased in radiation necrosis, while an inhomogeneous pattern with areas of high regional blood volume can be demonstrated in recurrences.²³

Arteriovenous malformations are quite easily demonstrated by MRI, including magnetic resonance angiography. However, due to inherent limitations of magnetic resonance angiography, the success of interventional therapy by embolization tends to be overestimated. In a recent study²⁴ we showed that contrast enhanced perfusion imaging is by far the most sensitive MRI technique to demonstrate residual pathologic vasculature after embolization. Perfusion imaging is also highly useful to demonstrate reopening of previously occluded pathways and is therefore part of our standard protocol in the evaluation and follow-up of arteriovenous malformations.

4 MYOCARDIAL PERFUSION IMAGING

Initial experience with gadolinium-DTPA at our Institution demonstrated increased enhancement in acute infarcts but no significant enhancement in subacute and chronic infarcts.²⁵ Since spin echo pulse sequences with an acquisition time of more than 5 min were used in these studies, the enhancement did not reflect blood flow but contrast extravasation into the interstitial space which is mainly a function of microvascular permeability. Other MR contrast media such as dysprosium, manganese, macromolecular gadolinium compounds, and superparamagnetic agents have been successfully studied.^{26,27}

Atkinson and co-workers performed bolus injection experiments using a T_1 -weighted pulse sequence;²⁸ they described a transient signal intensity increase during the first pass of the contrast material in normal myocardium of experimental animals and volunteers, but no signal intensity change after experimental occlusion of the left coronary artery. In a subsequent study, similar effects were seen in patients with coronary artery disease.²⁹ No attempt was made in these studies to quantify the effects in terms of myocardial blood flow.

Wilke et al. have used a kinetic model involving the mean transit time concept to obtain blood flow estimates in an experimental model. Blood flow was measured by a radiomicrosphere reference technique. A correlation coefficient of $r = 0.89$ was found between the MRI estimate of flow (the inverse of mean transit time) and the reference technique. It must be noted, however, that changes in myocardial blood volume are not accounted for in that model. Since myocardial blood volume is highly variable, myocardial blood flow estimates based on mean transit time alone are likely to be much less reliable in a clinical setting.

5 PERFUSION IMAGING OF OTHER ORGANS

Next to the brain and heart, perfusion imaging of the kidneys might be of clinical interest. Imaging of renal blood flow is quite complex because flow and function (=excretion) are tightly related. Gadolinium-DTPA is freely filtrated in the glomerulus and neither secreted nor reabsorbed in the tubular system.³⁰ Due to water reabsorption in the tubules, the concentration of gadolinium-DTPA increases by up to a factor of 100 from the initial plasma concentration. This wide range of concentrations is unique in the kidneys and has important effects on the observed signal intensity: at lower concentrations, signal intensity increases due to T_1 shortening; at higher concentrations, signal intensity decreases due to T_2 shortening. Obviously, this nonlinearity complicates the interpretation of signal intensity versus time curves measured in the kidneys. Nevertheless, three phases can be distinguished after contrast bolus injection: a vascular, a tubular, and a ductal phase.³¹ Due to the complexity of both renal physiology and the contrast mechanisms, assessment of renal blood flow will remain one of the most challenging tasks in MR imaging of organ blood flow.

The methodology discussed in this article also applies to perfusion imaging of other tissues. It must be noted, however, that the quality of the primary data (the concentration versus time curve) depends on the contrast concentration obtained during the first pass after bolus injection; tissues with low re-

gional blood flow and volume are therefore unlikely to be candidates for the assessment of perfusion by contrast bolus experiments.

6 FUNCTIONAL IMAGING OF THE HUMAN CORTEX

Functional imaging of the brain refers to the detection of stimulated cortical activity. The stimulus may be an optical, motor, or sensory paradigm; even ideation of motion or a visual pattern can act as a stimulus. Cortical stimulation entails alterations of regional cerebral blood flow, blood volume, oxygenation, and metabolism which can be detected by MRI. Classically a domain of nuclear medicine, in particular of positron emission tomography, MRI has been very successful in detecting evidence of cortical activation.³² The methodology relies upon the above-described contrast bolus experiment which is performed under resting conditions and during stimulation. The computed blood volume images are subtracted from one another; the subtraction image represents areas of locally altered perfusion due to cortical stimulation.

Cerebral Perfusion Imaging by Exogenous Contrast Agents

Leif Østergaard

Århus University Hospital, Århus, Denmark

1 INTRODUCTION

Cerebral blood flow (CBF) and cerebral blood volume (CBV) are traditionally used as physiologic indices of cerebral function. Positron emission tomography (PET), single photon emission computed tomography (SPECT) and stable xenon-enhanced computed tomography (Xe-CT) are frequently used for determining relative or absolute CBF, as well as flow changes in response to pharmacologic stimuli or functional activation.

With the increasing role of magnetic resonance imaging (MRI) in the diagnosis of cerebral pathologies, techniques to derive cerebral perfusion indices have also emerged. Rosen and co-workers^{1–4} derived maps of relative CBV by dynamic bolus tracking of susceptibility contrast agents, a technique known as perfusion imaging. Theoretical analysis of bolus-tracking experiments has subsequently been extended to allow measurements of CBF. In this article, the theoretical foundation of perfusion imaging by exogenous contrast agents is reviewed, together with areas of potential clinical use for the techniques.

2 THEORY

2.1 Contrast Mechanisms

The derivation of physiologic parameters from dynamic MR images requires detailed tracer kinetic analysis of tissue concentration–time curves obtained during passage of a bolus of contrast agent. Establishing the relation between signal changes observed with a given pulse sequence and the corresponding tissue contrast agent concentration is, therefore, necessary to derive quantitative information. Consequently, the study of interactions between contrast agents and tissue represents the foundation of perfusion imaging and remains a field of intense research. Although a full overview of this area is beyond the scope of this article, certain findings are of central importance to the application and understanding of perfusion imaging.

2.1.1 Susceptibility Contrast

Most cerebral perfusion imaging is carried out using dynamic susceptibility contrast imaging: tracking the passage of a rapidly injected paramagnetic gadolinium-based chelate. In

the presence of an intact blood–brain barrier, the intravascular compartmentalization of a paramagnetic contrast agent with high magnetic moment creates large, microscopic susceptibility gradients, with resulting signal loss in T_2 and T_2^* -weighted images. The dynamics in the presence of a leaky blood–brain barrier will be further explored in Section 2.7.

The microscopic susceptibility gradients cause local changes in water resonance frequency and in water frequency line width, with resultant signal loss and phase distortions for pulse sequences without full refocusing of static field inhomogeneities (gradient echoes, asymmetric spin echoes). For pulse sequences *with* full refocusing of static field inhomogeneities (spin echoes), these phenomena do not cause appreciable signal loss. Instead, signal loss is observed at long echo times (TE) because there is sufficient time for water to diffuse through areas of different magnetic fields (i.e. among contrast-filled vessels) and thereby dephase. This diffusion-related signal loss is a complex function of TE , the distribution and density of vessel sizes, and the concentration and magnetic properties of the contrast agent. Weisskoff, Boxerman, Fisel and co-workers performed a detailed analysis of these effects in the context of cerebral physiology, using Monte Carlo modeling as well as empirical data.^{5–7} Two results are particularly important in terms of interpreting perfusion imaging data. First, owing to the properties of susceptibility contrast mechanisms, spin echo measurements are mainly sensitive to vessels of a similar size to the water diffusion length ($\sim 10 \mu\text{m}$), whereas gradient echo measurements are equally sensitive to all vessel sizes. Figure 1 illustrates the change in transverse relaxation rate for gradient echo (ΔR_2^*) and spin echo (ΔR_2) caused by different concentrations of gadolinium and deoxyhemoglobin. Second, an approximately linear relationship exists between tissue contrast agent concentration and change in the T_2 relaxation rate

$$\Delta R_2(t) \propto C_t(t) \quad (1)$$

where for gradient and spin echo sequences, signal intensity $S(t)$ depends in an exponential fashion upon ΔR_2 and the longitudinal relaxation rate change ΔR_1

$$S(t) = S(t_0)(1 - \exp^{-TR \cdot \Delta R_1(t)}) \exp^{-TE \cdot \Delta R_2(t)} \quad (2)$$

where $S(t_0)$ is the baseline signal intensity and TR is the repetition time. If R_1 remains constant, this provides the desired relation between concentration and signal intensity

$$C_t(t) = -k \log \left(\frac{S(t)}{S(t_0)} \right) / TE \quad (3)$$

The constant k depends on the magnetic properties of the contrast agent, as well as its distribution space (plasma fraction).

The assumption of linearity in Equation 1 has since been further confirmed by indirect measurements *in vivo*;⁸ preliminary studies suggest that, in the brain, the microvascular CBV ‘visible’ by spin echo planar imaging is approximately 45% of the ‘total’ CBV as observed by PET.⁹

It is particularly important to bear in mind that tissue and major vessel hematocrit differ in the brain because of rheologic effects.^{10,11} This must be taken into account when simultaneously applying noninvasively determined tissue and arterial

Figure 1 Changes in the transverse relaxation rates (as derived from Equations 1 and 3) for (a) gradient echo [ΔR_2^* ; echo time (TE) 60 ms] and (b) spin echo (ΔR_2 ; TE 100 ms) sequences as a function of vessel size. Curves are shown for typical gadolinium (Gd) doses used in cerebral perfusion imaging (0.1 – 0.2 mmol kg^{-1}) and typical cerebral vascular volume fraction. Also shown are corresponding curves for the weakly paramagnetic deoxyhemoglobin (Deoxy Hb) used in functional MRI. Whereas spin echo measurements peak for small vessel sizes, gradient echo values reach a plateau and remain equally sensitive to all vessel sizes. In addition, ΔR_2^* values exceed ΔR_2 values for all vessel sizes. (With permission from Boxerman *et al.* 1995⁵)

concentration levels (Sections 2.2. and 2.3). In general, micro-vascular hematocrit is a complicated function of vessel size, flow, and pathophysiologic conditions and ranges from 40 to 100% of the systemic blood hematocrit.¹²

2.2 Cerebral Blood Volume Measurements

Figure 2 shows a typical dynamic susceptibility contrast imaging experiment. Upon injection of contrast agent into an

Figure 2 Typical bolus tracking experiment. (a) MRI images at different time points (indicated in seconds) during a Gd-chelate bolus passage. Arrows highlight symbols, which are defined in the graphs. (b) Following intravenous injection, contrast agent appears early in the arteries, causing appreciable signal loss. Tissue signal loss varies according to regional blood volume. This study was obtained from a patient with a brain tumor and shows high blood volume (CBV) in the temporal lobe (see Section 3.3). (c) The corresponding concentration–time curves are derived from Equations 1 and 3. (d) These tissue curves are integrated using Equation 4 to generate maps of CBV.

antecubital vein, the contrast agent reaches the brain, causing a substantial signal loss. The transit of the bolus is very rapid; consequently, rapid imaging (typically 1 image every 1.5 s) is required in order to capture the first pass of the bolus using fast low angle shot (FLASH) or multislice echo planar image sequences.

By detecting the arterial as well as the total tissue concentration as a function of time during a single transit, the CBV can be determined from the ratio of the areas under the tissue concentration–time and arterial concentration–time curves, respectively:^{13–16}

$$CBV = \frac{\int_{-\infty}^{\infty} C_t(\tau) d\tau}{\int_{-\infty}^{\infty} C_a(\tau) d\tau} \quad (4)$$

where $C_a(\tau)$ and $C_t(\tau)$ are the arterial and tissue contrast agent concentrations respectively.

It is inherently difficult to obtain arterial concentrations by dynamic susceptibility contrast MRI (see Section 2.5); consequently, uniform arterial concentration profiles in all arterial blood reaching the tissue is often assumed. The denominator of Equation 4 is thereby constant across regions, and relative CBV can be determined by simply integrating the area under the concentration–time curve,^{2–4} often by the use of a gamma variate function to correct for tracer recirculation.¹⁷

2.3 The Transport Function and Mean Transit Time

Figure 3 shows a schematic vascular residue. An infinitely sharp input is injected into the bloodstream of a tissue element at time $t=0$. The tracer follows the bloodstream through arterioles, capillaries, and venules, finally leaving the tissue vasculature through the vein. The associated probability density

Figure 3 Idealized, infinitely sharp bolus injection into the bloodstream of a schematic tissue volume. The tissue concentration as a function of time ($C_t(t)$) is in this case given by the flow (F_t) multiplied by the residue function $R(t)$. Notice $R(0)=1$ and $R(\infty)=0$. The tracer concentration in the vein is determined by the transport function, $h(t)$, which is given by the time derivative of $R(t)$: $h(t) = -R'(t)$. In actual experiments, the bolus reaching the brain will have a finite duration. The tissue concentration–time curve then becomes a convolved signal of the impulse response above (i.e. $F_t R(t)$) with the arterial input shape (Equation 9).

function of transit times is denoted by $h(t)$, the transport function. For an arterial input $C_a(t)$ with a finite duration, the venous output tracer concentration, $C_v(t)$, is described by the convolution of the local transport function by the arterial input function:

$$C_v(t) = C_a(t) \otimes h(t) \equiv F_t \int_0^t C_a(\tau) h(t - \tau) d\tau \quad (5)$$

where $\otimes$ denotes convolution and F_t is tissue flow. The mean transit time (MTT) for the tracer particles is defined as the first moment of the transport function:

$$MTT \equiv \frac{\int_{-\infty}^{\infty} \tau h(\tau) d\tau}{\int_{-\infty}^{\infty} h(\tau) d\tau} \quad (6)$$

As pointed out by Weisskoff *et al.* the distinction between MTT and the first moment of the tissue concentration–time curve is crucial in attempts to measure transit times using intravascular tracers.¹⁸ The calculation of MTT, therefore, requires knowledge of the transport function or CBF, as, by the central volume theorem.¹⁴

$$MTT = \frac{CBV}{F_t} \quad (7)$$

2.4 The Residue Function: Cerebral Blood Flow

For tomographic measurements of tissue tracer concentrations, the local retention is described by the residue function $R(t)$, the fraction of injected tracer still present in the vasculature at time t ; this is defined in terms of the transport function as

$$R(t) \equiv \left[1 - \int_0^t h(\tau) d\tau \right] \quad (8)$$

Note that by the definition of $h(t)$ as a probability density function, $R(0)=1$ and $R(\infty)=0$, just as $R(t)$ is a positive, decreasing function of time.

As shown in Figure 3, the concentration $C_{VOI}(t)$ of tracer within a given volume of interest can now be written

$$C_{VOI}(t) = F_t \int_0^t C_a(\tau) R(t - \tau) d\tau \quad (9)$$

The equation states that the tissue concentration–time curve is given by an impulse response function, $F_t R(t)$, convolved with the arterial input function, $C_a(t)$. In other words (as $R(0)=1$): the initial height of the deconvolved concentration–time curve equals the flow, F_t .

There are two main approaches to solve Equation 9 to determine regional flow. The model-dependent techniques use specific analytical expressions chosen to describe the shape of the residue function. In model-independent approaches, straight deconvolution is performed in every image pixel, solving Equation 9 for the impulse response function.

2.4.1 Model-independent Approach

In the model-independent approach, Equation 9 is solved for the impulse response function by standard mathematical deconvolution techniques, typically a transform approach or a linear algebraic approach.

In the Fourier transform approach,^{19,20} Equation 9 is rewritten

$$F\{F_t \cdot R(t) \otimes C_a(t)\} = F\{C_t(t)\} \Rightarrow F_t \cdot R(t) = F^{-1} \left\{ \frac{F\{C_t(t)\}}{F\{C_a(t)\}} \right\} \quad (10)$$

where F and F^{-1} denote the discrete and inverse discrete Fourier transform, respectively.

In the linear algebraic approach, Equation 9 is rewritten into a matrix equation.²¹ Assuming that tissue and arterial concentrations are measured at equidistant time points $t_1, t_2=t_1+\Delta t, \dots, t_N$, the tissue concentration $C_t(t_j)$ at time t_j in Equation 9 is reformulated as a matrix equation by noting

$$C_t(t_j) = F_t \int_0^{t_j} C_a(\tau) R(t_j - \tau) d\tau \approx F_t \Delta t \sum_{i=0}^j C_a(t_i) R(t_j - t_i)$$

This is equivalent to

$$\begin{pmatrix} C_t(t_1) \\ C_t(t_2) \\ \dots \\ C_t(t_N) \end{pmatrix} = F_t \cdot \Delta t \begin{pmatrix} C_a(t_1) & 0 & \dots & 0 \\ C_a(t_2) & C_a(t_1) & \dots & 0 \\ \dots & \dots & \dots & \dots \\ C_a(t_N) & C_a(t_{N-1}) & \dots & C_a(t_1) \end{pmatrix} \cdot \begin{pmatrix} R(t_1) \\ R(t_2) \\ \dots \\ R(t_N) \end{pmatrix} \quad (11)$$

which can then, theoretically, be inverted to yield $F_t \cdot R(t)$

Stable solutions to Equations 10 and 11 can only be obtained by applying techniques to suppress experimental noise. For the Fourier transform, this is achieved by applying a filter to the higher frequencies in the frequency (transformed) domain, assuming this can be done without losing physiologic information. For matrix equations such as Equation 11, noise is often suppressed by regularization (forcing the solution to satisfy a priori, user-defined conditions, or otherwise be well behaved)²² or by singular value decomposition.^{23,24} The optimal choice of some transform and linear algebraic approaches was studied by Østergaard *et al.* using Monte Carlo simulations.²⁴ It was found that the Fourier transform has an inherent problem in reproducing the discontinuity of the residue function at $t=0$, bearing in mind that

$$\lim_{t \rightarrow 0^+} R(t) = 1$$

whereas

$$\lim_{t \rightarrow 0^-} R(t) = 0$$

This discontinuity is represented at high frequencies in the transformed data and is, therefore, easily lost in subsequent fil-

tering. As reliable determination of the initial height of the response function is essential in determining flow, this property, in theory, introduces a tendency for F_t to be overestimated, and biased by the underlying vascular structure. Despite this drawback, the Fourier transform approach has the attraction of, theoretically, being insensitive to any delays between the arterial input function and the tissue arrival, as may occur in cerebrovascular disease. Preliminary results indicate that, in normal volunteers, the Fourier transform dependence upon vascular structure does not lead to appreciable differences in rCBF estimates from those obtained by the singular value decomposition approach.²⁵

In the linear algebraic approaches, regularization showed an inherent dependency on signal-to-noise ratio (and, therefore, on rCBV). Deconvolution by singular value decomposition showed, however, a remarkable independence of vascular structure and CBV, yielding reasonably accurate CBF estimates even at the signal-to-noise ratio of pixel-by-pixel clinical echo planar imaging measurements. The major disadvantage of the linear algebraic approaches is a tendency to underestimate flow when tissue tracer arrival is delayed relative to the arterial input function, a problem not associated with the transform approaches.

The deconvolution techniques make no assumptions regarding the vascular structure. Instead, regional vascular transit-time characteristics can be determined along with tissue flow by studying the residue function. Given the potential metabolic information of the residue function (see Section 2.6. on flow heterogeneity), this approach may be desirable in some cases.

Even though a straight delay of tracer arrival can, in theory, be accounted for, model-less approaches cannot distinguish tracer dispersion in feeding vessels from tracer retention in the capillary bed: large vessel dispersion will be interpreted as a low flow, although actual tissue flow is normal.²⁶ This is a more fundamental limitation that cannot be circumvented unless a specific model of major vessel dispersion is assumed. This will be described further below.

2.4.2 Model-dependent Approach

Models of tracer transport and retention must be chosen very carefully in order not to lose generality and thereby bias the resulting flow values.²⁷ Larson *et al.* suggested an exponential residue model, assuming the microvasculature to behave like a single, well-mixed compartment.²⁸ Although residue functions determined by model-less approaches (Section 2.4.1) often appear exponential, this model tends to bias resulting flow values in cases where the underlying residue function is nonexponential.²⁶ Østergaard *et al.* modified and applied a model of macrovascular transport and microvascular retention in the brain.²⁹ The model, originally introduced to describe tracer transport and retention in the heart,^{30–32} utilizes vascular transport operators, allowing detailed modeling of the delay and dispersion of the arterial input owing to the passage through the artery downstream of the measurement site.

Vonken *et al.* recently suggested a promising, more general family of analytical functions to fit residue functions, with the further advantage of allowing for delayed tracer arrival relative to the measured arterial input.^{33,34}

Whereas the model-less approach offers simultaneous determination of flow and vascular residue function, the vascular model approach requires a model of major vessel transport as

well as of microvascular retention. Major vessel dispersion and microvascular retention can then to some extent be distinguished, stabilizing CBF estimates. However, abnormal capillary perfusion patterns (and consequent deviation from the normal flow heterogeneity) are likely to affect flow estimates by this approach.^{18,27}

2.5 Quantification Issues

The formalism above produces absolute values for CBF and CBV provided arterial and tissue concentrations are experimentally determined in identical units. This, however, represents a number of practical problems in actual clinical applications. First, in order to obtain arterial and tissue concentrations in similar units, the hematocrit difference between the micro- and macrovasculature (and thereby the difference in plasma volume) must be taken into account (see Section 2.1.1).²⁰ Second, absolute arterial tracer concentration measurements are difficult to obtain from image data because of the inherently limited resolution of MRI relative to vessel sizes. Several studies have applied FLASH-type imaging sequences, allowing measurements of arterial levels in a separate, low slice with a short TE ; this avoids complete loss of vascular signal during the bolus passage.^{18,20,35} These studies yielded somewhat high values for absolute CBF, possibly as a result of the choice of the deconvolution approach, or because of partial volume and averaging effects. A recent study by Schreiber *et al.* obtained absolute values in good agreement with accepted flow rates.³⁶ In multi-slice echo planar imaging experiments, a single echo is generally used, optimizing tissue signal loss but often causing complete signal loss at major vessels. Therefore, smaller arterial branches with partial volume effects with surrounding tissue are used. The shape rather than the absolute amplitude of the arterial input function is obtained in these experiments. For comparison of results in different subjects, an internal reference must be chosen that is believed to have little inter-subject variability, for example white matter or cerebellum. In an attempt to obtain absolute flow values from echo planar imaging, Østergaard *et al.* assumed proportionality between the area of the arterial input function and the injected contrast dose, using water clearance PET as a calibration method. This approach provided reproducible absolute CBF measurements in animal hypercapnia studies⁹ and in humans.³⁷ It may, however, be too crude a method for general use in patients with severe cardiac or cerebrovascular disease.

2.6 Flow Heterogeneity: Metabolic Significance of the Residue Function

As diffusible solutes such as oxygen pass through the capillary bed, they are extracted by the tissue. The extraction fraction E (fraction of substance extracted during a single pass) of a solute is given by:^{38,39}

$$E = (1 - e^{-(PS/F_i)}) \quad (12)$$

where P is the permeability and S the surface area of the capillary endothelium. When the mean flow is very small compared with PS , extraction is near unity; when flow approaches or exceeds PS , extraction becomes incomplete.

Assuming that the capillary bed can be subdivided into a number of parallel microvessels with identical PS , and with individual relative flow rates f (flow divided by the mean flow F_i), Equation 12 generalizes to Equation 13 where $w(f)$ is the flow heterogeneity, the probability density function of relative flows. In this situation, the extraction fraction becomes:

$$E = \int_0^\infty w(f)(1 - e^{-(PS/fF_i)}) df \quad (13)$$

Assuming the PS product for a given molecule and tissue is essentially constant, the flow and associated flow heterogeneity become the prime determinants of solute extraction when PS is large (i.e. extraction is determined by flow rather than permeability). In particular, if flow is fixed (e.g. in acute stroke), extraction can only be modified by altering flow heterogeneity.

The residue function and the flow heterogeneity are related through the distribution of transit times (see Section 2.3). The transport function is the slope of the residue function

$$h(t) = -\frac{dR}{dt} \quad (14)$$

and the distribution of flows is by the central volume theorem¹⁴ given by

$$w(f) = -\frac{T}{f} \cdot h(T) \quad (15)$$

where T is the associated transit time for a relative flow of f . Combining Equations 14 and 15 will give flow heterogeneity in terms of the residue function. Flow and flow heterogeneity, in turn, can be used to determine the extraction fraction by Equation 13.

2.7 Bolus Tracking when the Blood–Brain Barrier is Leaky

For high-grade CNS tumors and in diseases such as multiple sclerosis, the blood–brain barrier breaks down, and vessels become permeable to standard gadolinium chelates. The compartmentalization necessary to perform dynamic susceptibility contrast studies partly breaks down and the T_1 -shortening properties of the contrast agents become prominent (Figure 4). This problem has been circumvented in three ways. First, dysprosium-based contrast agents, which have little T_1 enhancement, can be used rather than gadolinium-based contrast agents. As this inevitably affects subsequent conventional diagnostic imaging based on traditional T_1 enhancement, this approach is now uncommon. Second, a pre-dose of gadolinium-based contrast agent can be applied, saturating the interstitial space and thereby minimizing first-pass clearance during the subsequent bolus passage.⁴⁰ In the following, a third approach, namely modeling the simultaneous T_1 and T_2 enhancement, is described.

2.7.1 Tracer Extraction: Flow versus Permeability

The total tissue concentration as a function of time as contrast agent passes from the bloodstream into the surrounding extravascular space can be broken down into an intravascular, $C_{iv}(t)$, and an extravascular, $C_{ev}(t)$, component as follows:

Figure 4 Dynamic susceptibility contrast imaging in a patient with an astrocytoma grade III with leakage of gadolinium contrast across the blood–brain barrier. In normal tissue, signal loss is observed during the bolus passage (graph, lower left). Notice the T_1 enhancement in the tumor owing to contrast leakage (upper right), dominating over the normal signal loss caused by the T_2 shortening from compartmentalization of the gadolinium (lower right). If not corrected for, this would cause an underestimation of cerebral blood volume. (Courtesy Dr. J. D. Rabinov)

$$C_t(t) = C_{ev}(t) + C_{iv}(t) = K_1 \cdot \int_0^t C_a(\tau) \cdot e^{-k_2(t-\tau)} d\tau + F_t \int_0^t C_a(\tau) \cdot R(t-\tau) d\tau \quad (16)$$

where K_1 is the unidirectional clearance rate of tracer from blood to tissue and k_2 is the clearance rate from tissue to blood. The latter is given by K_1/V_d , where V_d is the distribution space for the tracer; for most contrast agents this is extravascular, extracellular space. The last term in Equation 16 is that given in Equation 9 to describe the concentration of intravascular tracer within a volume of interest. The first and second terms in Equation 16 are very similar; in transport into the extravascular space, the residue function is assumed to be that of a well-mixed compartment, namely an exponential. The terms K_1 and V_d in Equation 16 (the latter as part of k_2) are equivalent to F_t and CBV, respectively, in Equations 7 and 9.

Neglecting for a while the intravascular term in Equation 16, the physiologic interpretation of the unidirectional clearance K_1 depends somewhat on its magnitude. Bearing in mind that the extraction fraction is the unidirectional clearance divided by the tissue flow, Equation 12 can be rewritten

$$K_1 = F_t(1 - e^{-(PS/F_t)}) \quad (17)$$

When the term PS is much smaller than the mean flow, transport into the tissue is limited by the vascular permeability and surface area, and, from Equation 17, K_1 is approximately equal to PS , i.e. it is a measure of capillary surface area and capillary permeability. When PS is much greater than mean flow, clearance is independent of permeability and only flow through the tissues limits the appearance of tracer in the tissue. In this flow-limited case, K_1 approximates to mean flow. Interpretation of measured clearance rates, therefore, requires careful inspection as to whether these are comparable to likely flow rates. If, on the one hand, clearance values represent PS , they may serve to characterize vascular density and integrity. However, on the other hand, if they represent flow, the correlation with vascular characteristics is less clear, and they may be an indirect measurement of the supply of nutrients to the tissue.

2.7.2 Correction for Permeability

As gadolinium-chelate leaks into the tissue (first term in Equation 16), the T_1 shortening effects of the contrast agent

become dominant, ultimately overwhelming the signal loss resulting from the T_2 decrease associated with compartmentalization of the agent. This causes a net increase in signal intensity (Figure 4). Unless the effects of contrast leakage on T_1 are corrected for, the signal loss will result in underestimation of CBV.

Weisskoff *et al.* introduced an approximation to Equation 16 allowing simultaneous mapping of CBV and the permeability of the blood–brain barrier to gadolinium-chelates.⁴¹ The intravascular concentration term in Equation 17 was assumed to be proportional to the vascular signal in a non-leaky reference volume, $C_c(t)$. Assuming this vascular concentration constitutes the input function to the extravascular compartment in Equation 16, and further assuming that back-diffusion is negligible ($k_2=0$) during the short time of a bolus transit, the combined change in transverse relaxation rate, $\Delta R_{2,\text{total}}$ (as derived from Equations 1 and 3) can be shown to simplify to

$$\Delta R_{2,\text{total}}(t) = A \int_0^t C_c(\tau) d\tau + B \cdot C_c(t) \quad (18)$$

where A is proportional to K_1 and B to CBV, thus allowing simultaneous determination of permeability and CBV even in the presence of contrast leakage. Østergaard *et al.* presented an extension of this model, maintaining the second term in Equation 16 and allowing simultaneous measurement of permeability, CBF, and CBV.⁴²

2.8 Other Hemodynamic Indices

The derivation of flow and transit time from bolus tracking requires derivation of arterial input tracer levels. In some cases, this may not be practical, just as the inherent complexity of deconvolution approaches may preclude the use of these techniques in some situations. Parameters that can be derived directly from the tissue concentration–time curves include time-to-peak (time from injection to maximum concentration is reached), arrival time (arrival time of tracer in the pixel), full width at half maximum of the tissue bolus shape, and first moment of the peak. Although the dependence of these parameters upon MTT and CBF is strongly affected by the vascular structure and the arterial input function,¹⁸ they often suffice to delineate pathologic changes and provide important qualitative information in many diseases. It appears, however, that the derivation of CBF, CBV, and MTT from kinetic principles somewhat improves specificity and sensitivity of clinical studies, facilitating inter- and intrasubject comparison.⁴³

3 APPLICATIONS

Much of the success of cerebral perfusion imaging lies in the fact that it allows the association of high-quality structural conventional MRI with physiologic parameters of importance in diagnosing and assessing outcome in major diseases. In the following discussion, major areas of impact for perfusion imaging are outlined, along with the rationale of its use.

3.1 Acute Stroke

3.1.1 Background

Acute stroke is the third leading cause of death in the Western World and the major cause of adult disability. As the incidence of the disease increases exponentially with age, the increase in mean age will cause the incidence to approximately double within the first half of the 21st century. In light of these severe personal and socioeconomic consequences, therapeutic strategies are emerging, that seek to limit tissue damage in the acute phase of the disease. For all types of pharmacologic intervention, treatment must be given promptly, as neuronal death from ischemia progresses rapidly after symptom onset. Currently, recombinant tissue-type plasminogen activator is approved by the US Food and Drug Administration for administration within 3 h of symptom onset (later administration of the drug is associated with risk owing to intracranial hemorrhage). Studies by PET and diffusion-weighted imaging (DWI, see below), however, indicate that neuronal death continues beyond 3 h, probably as long as 24 h in some patients. There is, therefore, an urgent need for imaging techniques to guide treatment, especially in terms of pointing to the presence of tissue at risk of infarction and selecting patients who would benefit from aggressive treatment. This poses a special challenge to diagnostic methods, as conventional CT and MRI are insensitive to the extent of neuronal death or extent of metabolic derangement within the first critical hours after symptom onset.

3.1.2 The Role of Diffusion Weighted Imaging

DWI (see *Methods and Applications of Diffusion MRI*) has become widely accepted as the method of choice for demonstrating severe ischemia in acute experimental situations as well as in human stroke. It is believed that as the sodium–potassium pump breaks down as a result of the severe energy depletion, there is a subsequent loss of water homeostasis and cells swell. As total water diffusivity is dominated by water in the extracellular space, this reduction in extracellular space results in a marked reduction in the apparent diffusion coefficient of water, which corresponds to signal increase in DWI. Although there is evidence from animal studies that the apparent diffusion coefficient decreases gradually with the severity and duration of ischemia, and may indeed be reversible if tissue is reperfused early on, there are only sporadic reports of spontaneous reversal of DWI abnormalities in humans.

After onset of ischemia, irreversible tissue damage occurs rapidly, and abnormalities have been observed by DWI within minutes in animals⁴⁴ as well as in humans.⁴⁵ DWI abnormalities seen in patients imaged early after symptom onset often spread substantially within the following 24 h,^{46–49} demonstrating further neuronal loss. It is hoped that perfusion weighted imaging (PWI) will enable prediction of this subsequent spread of tissue damage and, thus, improve patient management.

3.1.3 Perfusion Weighted Imaging: Rationale and Findings

The role of PWI in cerebral ischemia lies mainly in identifying areas where blood flow and oxygen supply are compromised to such an extent that subsequent tissue damage is imminent.

Figure 5 Changes in cerebral blood flow (CBF), blood volume (CBV), metabolic rate for oxygen (CMRO_2), and oxygen extraction fraction (OEF) as a function of perfusion pressure. A, perfusion pressure at which CBF can no longer be maintained. B, the perfusion pressure at which tissue oxygen demands can no longer be met by the blood supply. (With permission from Powers, 1991⁵¹).

Figure 5 shows a schematic outline of the hemodynamic and metabolic events that can lead to irreversible tissue death owing to a sudden decrease of perfusion pressure in acute stroke.⁵⁰ Through cerebral autoregulation, CBF remains constant at perfusion pressures above approximately 60 mmHg, through a compensatory increase in CBV. Below this perfusion pressure, CBF can no longer be maintained, and with a further decrease in CBF, CBV ultimately decreases. As cortical CBF falls below roughly half of normal values, oxygen supply is no longer sufficient to drive metabolic needs, and the patient experiences neurological deficits. Brain tissue can only withstand this energy depletion for a limited time. With prolonged ischemia or further decrease in CBF (down to roughly 25% of normal flow rates), irreversible damage is imminent. MTT is the $\text{CBV}:\text{CBF}$ ratio (Figure 5) and is roughly inversely proportional to the perfusion pressure.^{51–54} As MTT thereby increases steeply as perfusion pressure drops, it has been proposed as a sensitive marker (together with CBF and CBV) of the severity of the hemodynamic impairment in patients who have suffered an acute stroke or have carotid stenosis (Section 3.2).

As discussed in Section 3.1.2, abnormalities by DWI increase within the first 24 h after infarction. Studies have further established that abnormal perfusion patterns can be observed by PWI in patients with acute stroke; the volume of tissue showing PWI abnormalities often exceeds that of abnormal DWI, which is referred to as a *perfusion–diffusion*

mismatch. More importantly, infarct growth (i.e. growth of DWI lesion) almost exclusively occurs into areas of PWI–DWI mismatch.

Sorensen *et al.* investigated a group of 23 patients using PWI and DWI within 12 h of symptom onset of stroke.⁵⁵ In two thirds, the infarct subsequently grew significantly and lesion volumes by DWI at follow up exceeded the initial values by more than 15%. One third of patients displayed a decrease CBV exceeding the DWI abnormality, and half the patients showed decreased CBF beyond the DWI-determined lesion. In both cases, more than 90% of patients displaying such PWI–DWI mismatches experienced lesion growth, demonstrated on subsequent follow-up scans (Figure 6). The study confirmed the presence of increased CBV around DWI-determined lesions in some patients, as implied by Figure 5. Furthermore, one patient was found to have a DWI abnormality exceeding in size the PWI abnormality, suggesting the combined modalities may be used in detecting spontaneous reperfusion prior to institution of treatment.

Although DWI–PWI mismatch represents a predictor of infarct growth, the volume of MTT or CBF overestimated final infarct size by almost a factor of two; by comparison CBV and DWI seemed to underestimate final infarct size somewhat.⁵⁵ In the effort to be able to predict final infarct sizes, this has led to attempts not only to detect the presence of PWI abnormalities but also to build predictive models, thereby identifying levels of CBV, CBF, and MTT associated with extreme risk of subsequent infarction.⁵⁶ It is likely that effective prediction will require a combination of these parameters, rather than a single parameter (c.f. Figure 5), together with data such as duration of symptoms, blood pressure, and temperature.

The observation that a PWI–DWI volume mismatch suggests risk of subsequent infarction has been suggested as a tool in patient management. Sunshine *et al.* demonstrated that acute measurement by DWI and PWI is feasible in patients immediately after stroke.⁵⁷ Based on DWI, time-to-peak PWI, and duration of symptoms, patients in this study were stratified into groups with no infarct, lacunar infarcts, and cortical infarcts; on the basis of this grouping, patients were selected for conservative treatment, intravenous thrombolysis, or angiography with intra-arterial thrombolysis, respectively. This triage procedure enabled the risk of thrombolysis or invasive diagnostic procedures to be avoided in some patients while maintaining a more aggressive approach in others.

3.1.4 Flow Heterogeneity in Acute Stroke

In Figure 5, the cerebral metabolic rate of oxygen and the oxygen extraction fraction are shown. With limited blood flow, the relative lack of oxygen is compensated by extracting a higher fraction of the blood oxygen pool.⁵⁸ Classically, oxygen extraction is measured by PET as the ratio between regional oxygen clearance and CBF. Using invasive techniques in animal models, it can be shown that a graded decrease in perfusion pressure causes progressive loss of rapidly flowing red blood cells in the brain, thus decreasing total flow heterogeneity and causing increased oxygen extraction (see Section 2.6).⁵⁹ The importance of heterogeneity in cerebral physiology is also reviewed by Kuschinsky *et al.*⁶⁰

Østergaard *et al.* examined flow heterogeneity in normal volunteers and in patients within 12 h of symptom onset in strokes.^{29,61} In normal brain tissue, the distribution of relative

Figure 6 MR images at two levels from a 78-year-old female, 3 h after acute onset of aphasia during a cardiac catheterization routine. A, G, Structural MR images. Diffusion weighted images (B, H) show irreversible cell death in a small anterior region (arrows). Perfusion weighted imaging showed low cerebral blood volume (CBV) (C, I) and blood flow (CBF) in both anterior and posterior watershed areas. Note the mismatch between areas of low CBV and CBF, respectively, easily visible as a prolongation of plasma mean transit times (E, K). Note the correspondence with the final infarct size on subacute diffusion weighted images (F, L) (With permission from Sorensen *et al.*, 1999⁵⁵).

flows was found to be markedly skewed towards high flow rates, in agreement with observations using invasive techniques. Within regions of increased MTT, subregions showed loss of the high-flow component of the flow distribution, causing increased homogeneity of flow velocities,⁶¹ in agreement with animal studies.⁵⁹ In parametric maps quantifying statistically significant acute deviation of flow heterogeneity from that of normal tissue, areas of extreme homogenization of capillary flows predicted final infarct size on follow-up scans in 10 out of 11 patients (Figure 7). Although this finding is surprising and needs further validation, it suggests that heterogeneity measurements by high signal-to-noise ratio PWI may be a value in assessing acute stroke.

3.2 Carotid Stenosis

High-grade stenosis of the internal carotid arteries is associated with high risk of ischemic events, accounting for a significant fraction of acute strokes. Despite the high risk of stroke in patients with carotid stenosis, surgical treatment by carotid endarterectomy has often yielded only marginal reductions in the subsequent incidence of ischemic events, indicating a need for methods to identify subgroups of high-risk patients.

The pathophysiologic events ultimately leading to neurologic symptoms and tissue damage are similar to those described for stroke (see Section 3.1.3). PET studies have demonstrated that severe stenosis causes a marked compensatory increase in CBV.⁶² The degree of decrease in the CBF:CBV ratio ($1/MTT$) has been used as an indicator of regional perfusion pressure: low values (down to 50% of normal ratios) corresponding to hazardous hemodynamic impairment.^{62,63} However, some results suggest that oxygen extraction fraction assessed by PET may correlate more closely

with the degree of hemodynamic impairment than does the CBF:CBV ratio.⁶⁴

The hemodynamic severity of carotid stenosis may also be assessed by monitoring the brain's reserve capacity, i.e. its ability to respond to stimuli increasing CBF, such as breathing carbon dioxide or therapy with acetazolamide (a carbonic anhydrase inhibitor causing a similar increase in arterial carbon dioxide partial pressure). In a group of eight patients with known carotid occlusion, Schreiber *et al.* found decreased CBF in six and increased MTT in seven patients; five patients showed a decreased cerebrovascular reserve capacity as determined by an acetazolamide challenge.³⁶ The study suggests that MR, which is also capable of providing accurate delineation of vascular stenosis by MR angiography, may provide a powerful tool in assessing the hemodynamic severity of carotid stenosis, thus improving the identification of patients who may benefit from endarterectomy or stenting.

3.3 Cerebral Neoplasms

Tumor growth is limited by the ability of a neoplasm to stimulate surrounding tissue to form new blood vessels. Tumor angiogenesis by release of humoral factors (vascular endothelial growth factor) is one of the hallmarks of tumor growth and the target of novel approaches to treat human neoplasms. Noninvasive methods to assess the size, density, and integrity of tumor microvessels are, therefore, essential to detect malignancies, understand tumor growth, and to target and monitor new therapeutic approaches.⁶⁵

3.3.1 Tumor Vessel Density

The specific sensitivity of spin echo, echo planar imaging to microvessels provides a unique potential to study the proliferation of capillary sized vessels in tumor angiogenesis. As the

Figure 7 Initial diffusion weighted images (DWI) from a patient 5.5 h after onset of symptoms compatible with acute stroke (a). The patient suffers from a partial anterior cerebral artery (ACA) occlusion: note the prolonged mean transit time (MTT) in ACA territory (b) and that no acute DWI abnormalities are seen, indicating potential reversibility of the symptoms. The graph shows plots of flow heterogeneity probability density functions for normal MTT (red area indicated on MTT map) and two areas showing prolonged MTT (green, yellow areas). Note the narrow flow distributions in areas displaying prolonged MTT relative to normal tissue. This presumably results in higher oxygen extraction fraction. Areas of abnormal flow heterogeneity (1–5; defined as $p < 0.01$ by a Kolmogorov–Smirnov test comparing the pixels flow heterogeneity with that of normal tissue) are shown on a cerebral blood flow map (c). Note the striking correspondence with the final pattern of neuronal death (indicated by numbers to show areas in (b)) on the follow-up DWI (d).

ability to form new vessels is closely related to the growth potential and thereby aggressiveness of the tumor, the relation between histologic tumor grade and regional CBV has been studied extensively. Aronen *et al.* studied 19 patients with cerebral glioma and showed that CBV correlated with tumor grade as determined by biopsy or surgery.⁴⁰ In addition, a positive correlation was found between CBV and microscopic vascularity as well as with mitotic activity (Figure 8).

These studies also suggested a close correlation between microvascular CBV and the unidirectional clearance of fluorodeoxy glucose (FDG) as measured by PET, the gold standard for noninvasive staging and prediction of outcome in cerebral neoplasms (Figure 8). This correspondence may not be entirely coincidental: FDG transport across cerebral microvessels is limited by endothelial transporters and is, therefore, related to vascular surface area. Its uptake therefore to some extent represents a measurement of capillary density,⁶⁶ as do spin echo CBV measurements.

Subsequent reports have confirmed that CBV mapping may aid in noninvasive staging of tumors,^{67,68} and in the differential diagnosis of neoplasms and infectious changes.⁶⁹ CBV mapping in conjunction with conventional imaging may aid diagnosis by allowing accurate biopsy planning^{31,67} and can be used for assessment of the effects of treatment such as radiotherapy.⁷⁰ Consequently, MR perfusion imaging may provide a tool for the important, but often difficult, distinction between radiation necrosis and tumor regrowth.^{71,72}

Dennie *et al.* recently proposed an experimental methodology whereby the combined use of gradient and spin echo techniques for PWI could be used for more accurate, quantitative characterization of vascular morphology in tumor angiogenesis.⁷³

With further development of these techniques, there is reason to believe that CBV mapping may become an important supplement to conventional MRI, particularly in delineating and staging tumors, in defining appropriate biopsy sites, in the

Figure 8 MR of the brain in a patient with a grade III astrocytoma. (a) The T_2 -weighted image showing a small, contrast-enhancing lesion within the tumor volume, indicating edema. (b) A postcontrast T_1 -weighted image. (c) The CBV map identifies a region of significantly increased microvascular blood volume within the region of contrast leakage. (d) A PET scan using fluorodeoxyglucose to assess capillary density. There is a striking correspondence between the CBV map (c) and the area of high fluorodeoxyglucose uptake. assessment of angiogenesis, and, finally, in monitoring conventional as well as novel, anti-angiogenic therapies.

Research interests: perfusion, diffusion, water exchange phenomena and functional MRI.

CSF Velocity Imaging

William G. Bradley, Jr

Long Beach Memorial Medical Center, CA, USA

1 INTRODUCTION

Cerebrospinal fluid (CSF) is produced by the choroid plexus within the ventricles of the brain at a rate of 500 ml per day. It flows out of the foramina of Lushka and Magendie in the fourth ventricle and is absorbed by the arachnoid villi on either side of the superior sagittal sinus.¹ Superimposed on this slow, steady egress of CSF from the ventricular system are much more prominent cardiac pulsations resulting from systolic expansion and diastolic contraction of the brain. When the local CSF velocity is sufficiently high, e.g. through the narrow aqueduct of Sylvius, a 'CSF flow void'^{2,3} is normally produced, similar to that seen with rapidly flowing blood.⁴ When there is obstruction to CSF flow, the flow void is not observed.³ Obstruction proximal to the outlet foramina of the fourth ventricle is termed 'obstructive hydrocephalus'; obstruction between the outlet foramina of the fourth ventricle and the arachnoid villi is termed 'communicating hydrocephalus'. Communicating hydrocephalus most often follows subarachnoid hemorrhage or meningitis; however, a number of elderly patients may present with a radiographic pattern of communicating hydrocephalus without a history of either of these preceding events. Such hydrocephalus is termed 'occult' or 'idiopathic'.^{5,6} Since the mean intraventricular pressure is normal, it has also been called 'normal pressure hydrocephalus' (NPH).

Classically, NPH patients present with a clinical triad of gait apraxia, dementia, and incontinence.⁵⁻⁷ Although the mean intraventricular pressure is normal in these patients, the pulse pressure, i.e. the change in CSF pressure over the cardiac cycle, is much greater than normal. A 'waterhammer' pulse has been described in such patients when their intraventricular pressure is monitored.^{8,9} Until now the diagnosis of NPH has been made on the basis of a radiographic picture of ventricles enlarged out of proportion to any cortical sulcal enlargement (to distinguish NPH from atrophy).

Prior to the advent of MRI, this radiographic picture and the appropriate clinical triad alone were not sufficient to predict which patients would respond to the primary treatment for NPH, i.e. ventriculoperitoneal (VP) shunting. Recently, the magnitude of the aqueductal CSF flow void (Figure 1) has been used to predict which patients with clinical NPH will respond to shunting.¹⁰ The CSF flow void is a normal phenomenon, resulting from the pulsatile motion of CSF back and forth through the ventricular system over the cardiac cycle.¹¹ In the normal patient, there is space over the cortical convexities occupied by the cortical veins and the CSF in the subarachnoid space (Figure 2). When the brain expands during systole, it expands outward, compressing the cortical veins (leading to subsequent venous outflow), and it expands inward, compressing the lateral ventricles (leading

to outflow of CSF through the aqueduct which produces the normal flow void).¹⁰ In communicating hydrocephalus, the brain has already expanded against the inner table of the calvarium, so further outward expansion is not possible. Thus, during systole all cerebral expansion is directed inward, compressing the lateral ventricles, leading to increased outflow of CSF through the aqueduct. This is the etiology for the increased CSF flow void⁷ in patients with communicating hydrocephalus and normal cerebral blood flow (Figure 2). When the blood supply to the brain decreases due to atrophy, the main force behind the CSF pump decreases and the CSF flow void is consequently also reduced. In a recent study, there was a significant correlation between an increased CSF flow void, i.e. one extending from the third ventricle through the obex of the fourth ventricle, and a successful response to ventriculoperitoneal shunting.⁷ Patients with clinical NPH who did *not* have a hyperdynamic flow void, on the other hand, failed to respond to shunting. This association was significant at the $p < 0.003$ level.¹⁰ Thus, in the setting of an appropriate clinical triad for NPH and ventricular enlargement out of proportion to cortical sulcal dilatation, the presence of an increased aqueductal CSF flow void on MRI should prompt the neurosurgeon to perform a VP shunt. It should be emphasized, however, that younger patients with communicating hydrocephalus and intact cerebral blood supply may also have hyperdynamic CSF flow. Thus, the sign is not specific for NPH. Since NPH is a disease of elderly patients, it appears that symptoms follow a combined insult related to the ventricular enlargement and also to decreased perfusion of the periventricular region, i.e. the same process that leads to deep white matter ischemia and infarction.¹²

Figure 1 CSF flow void in normal pressure hydrocephalus. Proton density-weighted axial image through the upper fourth ventricle demonstrates marked CSF flow void (arrow)

Figure 2 Schematic representation of CSF flow mechanism. (a) In normal patients, systolic expansion of cerebral hemispheres occurs outward, compressing cortical veins and, to a lesser extent, inward, compressing the lateral ventricles. (b) In communicating hydrocephalus, the brain has already expanded against the inner table of the calvarium. Since outward expansion of the brain is no longer possible, the entire increase in volume due to systolic expansion is directed inwards, towards the lateral ventricles. The combination of this greater inward displacement and the mild aqueductal enlargement that accompanies communicating hydrocephalus leads to hyperdynamic CSF flow

2 MR TECHNIQUES USED TO MEASURE CSF FLOW

A number of magnetic resonance (MR) observations and techniques have been employed to take advantage of signal changes associated with CSF flow. The aqueductal CSF flow void (Figure 1) noted on routine MR images was the first indication of CSF motion.^{2,3} Subsequently, the CSF flow void was shown to be related to the cardiac cycle.¹³ Although a CSF flow void may be appreciated on routine spin echo and gradient echo MR images, the degree of signal loss is not consistent, nor does it change in a linear fashion with velocity.¹ Thus by using the CSF flow void sign alone, it may be difficult to appreciate when CSF flow is mildly abnormal. When a CSF flow void is not visualized at all in areas where it is normally

expected (e.g. the aqueduct), however, inferences can be made concerning obstruction.³ Axial, single slice, gradient echo techniques which maximize flow-related enhancement⁴ (entry phenomenon) have also been used¹⁴ to evaluate aqueductal patency. However, the best observations of CSF flow have been obtained using dedicated techniques, gated to the cardiac cycle.

In 1985, Feinberg and Mark^{15,16} used MR 'velocity density imaging' to measure the velocity of CSF through the aqueduct as a function of the cardiac cycle. Subsequently Edelman et al.¹⁷ used saturation pulses and bolus tracking techniques, while Axel and Dougherty¹⁸ used spatial modulation of magnetization (SPAMM) to measure CSF velocity. Today, most investigators are using phase contrast techniques.¹⁹⁻²¹

The phase contrast CSF velocity imaging techniques¹⁹⁻²¹ can be divided on the basis of the form of cardiac gating used, i.e. prospective or retrospective,²² and on the basis of background phase determination.²³ Most investigators^{19,20} determine the background phase from an additional acquisition. This approach necessitates obtaining two interleaved acquisitions and then subtracting them. We make the assumption of zero net flow²¹ over the cardiac cycle and calculate the background phase (which entails a single acquisition in one-half the time).

The relationship between the phase shift θ and velocity v is given by:

$$\theta = \gamma \int_0^t G(t) v t \, dt \quad (1)$$

where γ is the gyromagnetic ratio, $G(t)$ is the gradient strength as a function of time t , and t is the elapsed time.²⁴ Thus for an appropriate gradient pulse of strength G and duration t , a linear relationship should exist between the phase shift (from zero to $\pm 180^\circ$, depending on the direction of flow) and the actual CSF velocity. A new parameter, the V_{enc} , is the aliasing or 'encoding' velocity, which leads to a 180° phase shift.

With prospective cardiac gating, acquisition starts at a predetermined time interval after the R wave and continues at approximately 50–75 ms intervals to within about 200 ms of the next R wave (to allow for respiratory variation).¹⁹ Since there is no sampling of CSF motion during the final 100 or 200 ms of the R–R interval (when flow is in a rostral or retrograde direction), there appears to be a large net flow of CSF in the systolic direction (i.e. craniocaudal) over this partially sampled cardiac cycle.²¹

With retrospective cardiac gating,²² the computer keeps track of the R wave and data are acquired throughout the cardiac cycle and then retrospectively 'binned' into a predetermined number of frames.²² The entire cardiac cycle is sampled; therefore, there is no time for eddy currents to build up, as they do during the 200 ms dead time when prospective cardiac gating is used.²¹

We routinely use two retrospective cardiac gated techniques:²¹ a 'routine resolution' sagittal acquisition in the midline (see Figure 3); and a 'high-resolution' axial acquisition through the aqueduct (see Figure 4). In the sagittal technique, a 4 mm slice is acquired in the midsagittal plane (Figure 3) with velocity sensitization along the read-out axis (which is also the craniocaudal axis of the patient). Cardiac gating is performed with ECG leads rather than using finger plethysmography,

Figure 3 Sagittal phase contrast technique. (a) During systole, CSF flow is downward (craniocaudal), as indicated by shades of white. (b) During diastole, CSF flow is upward (caudocranial), as indicated by shades of black. By placing a cursor over any point in the image, the velocity can be obtained as a function of the cardiac cycle

since the systolic motion of the brain may actually precede the systolic pulse in the finger.²¹ The basic technique is a flow-compensated, two-dimensional fast imaging with steady precession (FISP) with a repetition time (TR) of 70 ms, a echo delay time (TE) of 13 ms, and a 15° flip angle (Figure 3). A 192×256 matrix is acquired over a 25-cm field of view, providing

Figure 4 Axial phase contrast technique. (a) High-resolution axial image obtained during diastole indicates upward flow (black) in the aqueduct (arrow). (b) During systole, flow is downward (white). The mean velocity (left upper), peak velocity (right upper), and volumetric flow rates (left lower) through the aqueduct are shown as a function of the cardiac cycle

in-plane spatial resolution of approximately 1 mm. The aliasing velocity is 100 mm s^{-1} . Such images are used routinely in the head to document midsagittal CSF flow. Using a single excitation and 32 acquisitions before phase advance, this sagittal technique takes 7 min. When a cursor is placed over any point on the phase contrast velocity image, craniocaudal CSF velocities can be measured and plotted versus the phase of the cardiac cycle, allowing comparison of phase relationships of CSF motion at different points in the ventricular system and subarachnoid space²¹ (Figure 3).

The measured velocity through the aqueduct on this sagittal acquisition also reflects the stationary tissue in the midbrain on either side of the aqueduct in a 4 mm thick slice. Therefore,

ation of the flow coming in from the aqueduct. Such asynchrony may result from pulsations of the choroid plexus of the fourth ventricle.²⁰ In fact, the caudally directed CSF pulse wave is observed to start first in the fourth ventricle, followed approximately 100 ms later by caudal flow in the aqueduct.²⁰ Cranial flow of CSF back through the aqueduct may still be occurring when the first downward pulsation through the foramen of Magendie is seen. Clearly, therefore, this cephalad aqueductal CSF flow is not simply the result of retrograde flow from the basal cisterns into the fourth ventricle and upwards.²⁰ The probable reasons for these normal

Figure 8 The 'rebound sign' in an arachnoid cyst. The qualitative (sagittal) technique has been rotated into the coronal plane with velocity encoding along the craniocaudal read-out axis. White, downward flow; black, upward flow (no flow is gray). (a) During systole, flow in the fourth ventricle (large arrow) is down while flow in the arachnoid cyst (small arrow) has stopped due to maximal deformation by the surrounding CSF. (b) 200 ms later, flow in the fourth ventricle has stopped (turning gray), while flow in the cyst has already started heading up (turning black). (c) 200 ms later, both the flow in the cyst and that in the fourth ventricle are up. (d) 100 ms later, the cyst has become maximally deformed and has stopped flowing (turning gray), while flow continues in the caudocranial direction in the fourth ventricle. (e) By placing cursors on the fourth ventricle and the cyst, motion in the cyst is seen to be of lower amplitude and 90° phase-advanced relative to the flow within the fourth ventricle

resolution axial technique which provides a measurement of the aqueductal CSF stroke volume. In a recent study of 20 patients with clinically suspected NPH, 14 were found to have hyperdynamic CSF flow, i.e. stroke volumes greater than 40 μL , while six were found to have hypodynamic flow.²⁶ Of the patients with hyperdynamic flow, 13 of 14 responded favorably to the ventriculoperitoneal shunt. (The one patient who did not was known to have chronic multiple sclerosis.) Thus this technique has an excellent positive predictive value. Of the six patients who had hypodynamic flow, three responded to shunting and three did not, probably reflecting the presence of concomitant atrophy in these patients. Interestingly, of the 14 patients with hyperdynamic flow (as determined by the measured stroke volume), only seven (50%) had hyperdynamic CSF flow voids on their routine MR images. This most likely reflects the current widespread use of first-order flow compensation on the proton density-weighted images which was not available on the 1984 images in the earlier study.¹⁰ Thus, quantitative CSF velocity imaging is an even better technique than routine MRI to determine the presence of shunt-responsive normal pressure hydrocephalus.

CSF velocity imaging is also useful in the evaluation of potential shunt malfunction.²⁷ In patients who have been shunted for communicating hydrocephalus, the normal pattern of CSF flow through the aqueduct is exactly 180° out of phase with normal with respect to the cardiac cycle, i.e. CSF flows caudo-

craniad during systole and craniocaudad during diastole (Figure 6). This probably reflects the fact that the shunt tube is the lowest resistance pathway to outflow of CSF following systolic expansion of both the cerebrum and the cerebellum. In patients with either obstructive or communicating hydrocephalus, the high-resolution axial technique can also be used to assess flow through the shunt tube itself (Figure 7). In cases of normal shunt function, CSF motion tends to be intermittent and unidirectional, rather than sinusoidal (as is normally seen through the aqueduct), reflecting the presence of the one-way valve.

Since the plane and position of both CSF velocity imaging techniques can be modified, they can also be used to distinguish cysts from enlarged CSF spaces. Within a cyst, the motion of CSF appears to rebound against the flowing CSF around it. This 'cyst rebound sign'²⁸ is the combination of decreased CSF velocity (within the cyst) 90° phase-advanced relative to the motion of the surrounding CSF (Figure 8).

Head and Neck Studies Using MRA

Paul M. Ruggieri, Jean A. Tkach, and Thomas J. Masaryk

Cleveland Clinic Foundation, Cleveland, OH, USA

1 INTRODUCTION

Magnetic resonance angiography (MRA) is most commonly applied to the evaluation of cerebrovascular disease as neurological examinations continue to be the mainstay of clinical MRI. In addition, the rapid blood flow through the extra-/intracranial cerebral vasculature, the paucity of gross physiological motion, and the existing coil technology make these vessels ideally suited to vascular MRI. MRA is especially appealing since it provides a morphological representation of the vasculature as a relatively rapid, noninvasive alternative to the existing vascular imaging modalities. During the same examination, conventional spin echo images of the brain parenchyma are acquired to assess the consequences of the underlying vascular pathology.

1.1 Carotid MRA: Technical Considerations

Two basic types of MRA sequences are commonly employed to study the cerebral vasculature: phase contrast (PC) and time-of-flight (TOF).^{1,2} The PC technique provides optimal suppression of the background stationary tissues via subtraction of alternating flow encoded images, and can be designed to be highly sensitive to blood moving at specific velocities. Appropriately calibrated sequences can also be designed to measure flow velocities. However, this technique demands longer acquisition and postprocessing times than the TOF studies of comparable spatial resolution. The phase sensitivity of this method also makes it more vulnerable to intravascular signal loss due to complex motion (e.g. carotid bifurcation stenosis) and/or local field inhomogeneities (e.g. carotid siphon, densely calcified atherosclerotic plaque).³ Consequently, the PC study is not commonly used to evaluate the carotid bifurcations in routine clinical work. A 2D PC study is useful as a quick scout view for subsequent positioning of the 2D or 3D TOF volumes and to confirm vessel patency. The 2D PC technique may also prove to be useful for making flow velocity measurements in the region of a carotid stenosis (similar to duplex ultrasound studies).

The TOF techniques take advantage of the rapid, constant inflow of fresh unsaturated spins to provide the necessary contrast relative to the adjacent stationary tissues. In lieu of subtraction mask acquisitions, angiographic images are rendered using computer postprocessing algorithms which may then create multiple MRA images from a single data set. The TOF methods are capable of minimizing intravoxel phase dispersion (and intravascular signal loss) by incorporating very

small voxels and very short echo times with motion refocusing gradients.⁴ Alternatively, the TOF sequences are not as sensitive to slow flow as the PC techniques. The TOF images also have less effective background suppression. Because the TOF studies are inherently T_1 -weighted, and the commonly used postprocessing method (maximum intensity projection or MIP) cannot necessarily distinguish bright vessels from other tissues with short T_1 relaxation times (e.g. fat, subacute hemorrhage), the vessels in the volume may be obscured by adjacent tissues. The MIP reconstruction technique may introduce additional artifacts in all MRA images. Small vessels may frequently be visible in the original slices but are not represented in the MRA image because of: (1) variation in background intensities; (2) marginal flow-related enhancement; and (3) partial volume averaging artifacts.⁵

Neither the PC nor the TOF technique can provide the contrast and spatial resolution needed to identify very subtle contour abnormalities which would be important in confirming mild vascular dysplasias (e.g. fibromuscular disease) or vasculitis that would only be evident using conventional arteriography. These limitations are predominantly related to signal-to-noise ratio (S/N) issues and the hardware (e.g. gradients, computer memory, processing speed) constraints imposed on the MRA pulse sequences. The two techniques are also unable to provide the same dynamic information as with catheter angiography.

1.2 Carotid MRA: Clinical Significance

MRA has the potential to make its greatest impact on routine clinical work in the evaluation of carotid bifurcation atherosclerotic disease. Justification for imaging the carotid bifurcations is based on the conclusions of the North American Symptomatic Carotid Endarterectomy Trial (NASCET) and the European Carotid Surgery Trial (ECST). These controlled randomized clinical studies support the clinical utility of carotid endarterectomies in symptomatic patients with severe (>70%) carotid bifurcation stenosis, and set well defined standards for the preoperative evaluation of these patients (angiographic demonstration, specific measurements of the stenosis, significant tandem lesions).⁶⁻¹⁰

Ideally, it would be preferable to replace the conventional catheter arteriogram with a noninvasive alternative, thereby avoiding the potential risks of the invasive study. As many of the symptomatic patients with cerebrovascular disease are evaluated by spin echo MRI to assess the severity of the parenchymal sequelae, MRA of the carotid and intracranial vasculature would be a logical (noninvasive) extension of such studies. However, this makes the assumption that MRA can provide the same information as the invasive study and has similar sensitivity and specificity. The questions that remain to be proven in large scale, prospective clinical trials include the following: (1) can MRA characterize carotid stenoses of 70–99% severity, (2) distinguish complete occlusion from severe stenosis, and (3) exclude tandem stenoses as accurately as catheter angiography? Among these questions, the issue with the least objective data is the ability of MRA to exclude the presence of tandem stenoses, most commonly in the carotid siphon. The presence of distal stenoses have been associated with an increased risk for cerebrovascular and cardiac complications, suggesting a subpopulation with more malignant

atherosclerosis.^{11,12} Moreover, although 3D TOF and PC MRA continue to improve, there are frequently artifacts mimicking stenoses of the carotid siphons due to complex flow and/or local field inhomogeneities.^{13,14} In the evaluation of carotid bifurcation disease, MRA is currently most appropriately assigned the role of a screening study for significant atherosclerotic disease which would be best followed up by conventional angiography, preoperatively.

1.3 Carotid MRA: Technical Considerations

In 2D TOF imaging, the carotid arteries are visualized by acquiring a series of thin 2D axial gradient echo images sequentially (superior to inferior) against the direction of flow. The high signal from the venous structures (particularly the jugular vein) can obscure the carotid bifurcation, but a traveling saturation pulse is placed superior to each excitation slice to eliminate the signal from the caudally directed venous flow.¹⁵ The motion-induced dephasing (intravascular signal loss) is minimized through a combination of constant velocity flow compensation gradients along the slice-select and frequency-encoding directions, the shortest possible echo times (8.0–9.0 ms with conventional gradients), and the smallest possible voxels (1.5–3.0 mm slice thickness and 1.0 mm in-plane resolution).

The major advantage of 2D TOF sequences relate to their sensitivity to slow flow as the spins must only move a short distance (1.5–3.0 mm 2D slice) within each *TR* interval to ensure high intravascular signal in each slice. Consequently, these sequences are readily able to distinguish a severe stenosis from an occlusion. A disadvantage of the 2D technique is the stair-step misregistration artifact or vessel discontinuities in the final MRA arteriogram images that arise due to gross patient motion during the acquisition of the individual slices. More importantly, the 2D sequences demand high gradient amplitudes to define the thin 2D slices, which, in turn, place significant restrictions on the minimum echo time and in-plane voxel dimensions. The high gradient amplitudes accentuate any spin dephasing due to motion which is not corrected by the flow compensating gradients. As a result, severe stenoses are often seen as 'flow voids' or vascular interruptions. In spite of this, 2D TOF MRA has been demonstrated to be a highly sensitive and very acceptable screening study.¹⁶

3D TOF sequences incorporate the same strategies for vessel visualization as their 2D counterparts, but the rf pulse excites a thick slab of tissue during each *TR* interval and the thin slices within the volume are defined by a second phase-encoding gradient along the slice-select direction. The examination time increases in proportion to the number of phase-encoding steps in the second direction (number of slices), but there is also a proportional increase in the S/N when contrasted to comparable size voxels in 2D sequences. As a result of the reduced gradient demands, the 3D sequences permit shorter echo times (4.5–7.0 ms) and higher spatial resolution (<1.0 mm³) with comparable refocusing pulses when contrasted to the 2D TOF sequences. These factors combine to minimize the degree of intravoxel phase dispersion and signal loss within the vessel.¹⁷ The phase errors increase quadratically with time in the setting of higher order motion terms so intravascular signal loss is especially likely within and immediately distal to a stenosis, within a focal tortuosity, and in some normal vessel

bifurcations. Since the greatest amount of dephasing occurs during the application of the gradients, the phase errors are most effectively suppressed by minimizing the duration, amplitude, and timing of the gradients.¹⁸ Additional flow compensation gradients can be incorporated to correct for the higher order motion terms but only at the expense of significantly stronger and longer gradients before the echo. The signal loss with the longer gradients more than offsets the minimal improvement derived from the supplementary motion compensation. Because these sequences are all gradient echo acquisitions, the intravascular signal is also reduced by *T*₂* phenomena. This effect is similarly reduced with small voxels and short echo times.¹⁹

The rapid unidirectional flow in the carotid arteries is particularly well suited to a 3D TOF acquisition. This technique also has its limitations which primarily relate to the saturation of flowing spins (e.g. slow antegrade flow distal to a severe stenosis). Spatially variable rf pulses (lower flip angle as the spins enter the volume and higher flip angles distally in the volume) have proven particularly helpful in this regard. The vessel/soft tissue contrast is somewhat reduced at the caudal end of the volume, but the contrast increases superiorly and the spins can flow further into the volume before becoming saturated without increasing the *TR*. Higher flip angles at the cranial end also increase the saturation of the stationary tissues for a given *TR*. The advantages of this rf pulse are particularly noticeable with slow flow such as in an elderly patient with poor cardiac output, a very small vessel lumen, or distal to a severe stenosis.

Failure to adequately suppress the background stationary tissues is a limitation of any TOF technique, but particularly the 3D technique in view of the lower signal of the blood (relative to 2D TOF). Excitation with higher flip angles improves the flow-related enhancement but accentuates the problem of spin saturation in 3D acquisitions. Shorter repetition times enhance the background suppression while causing more saturation of the flowing spins. In the neck, fat is the most problematic, as its short *T*₁ relaxation time and high spin density causes it to appear bright on the final MRA images. Since there tends to be a large amount of perivascular and subcutaneous fat in older patients (the group most likely to be studied for carotid atherosclerotic disease), the fat can largely obscure the underlying vessels. Reconstructing a subvolume that is limited to the region immediately surrounding the vessels excludes much of the stationary tissue from the reconstruction but does not eliminate the problem. Incorporating additional fat suppression pulses into these sequences will reduce the signal of the fat without affecting the vessel signal and can significantly improve the vessel/soft tissue contrast-to-noise level.²⁰ In practice, these pulses can be unreliable in clinical studies since local field inhomogeneities in the neck may cause inhomogeneous fat suppression or even water (blood) suppression.

In light of the above arguments, a most promising clinical method is the stacked overlapping 3D volume technique, which combines many of the advantages of the 2D and 3D studies.²¹ Relatively small volumes minimize the problem of spin saturation while the lower gradient demands of the 3D sequences allow for very short echo times and small voxels. Moreover, the stacked volume approach can be implemented with higher flip angles and/or shorter *TR* values than are possible with a large single 3D volume so the vessel/soft tissue contrast is

enhanced. If the stacked volumes incorporate the specialized rf pulses as discussed above, intermediate sized volumes can be used to improve the postprocessing, increase the anatomical coverage, and reduce the overall examination time.

1.4 Carotid MRA: Clinical Applications—Carotid Bifurcation

A number of studies have evaluated the clinical efficacy of 2D TOF MRA for imaging the carotid bifurcations, the largest of which was a study by Laster et al. in which the images from 101 patients were compared with conventional catheter angiography and, in some cases, Doppler ultrasound.^{22,23} As in any MRA technique, the degree of luminal narrowing tends to be accentuated compared with the conventional arteriogram images. Because of the limitations in echo time and voxel size with the 2D technique, the dephasing caused by higher order motion terms induces more prominent intravascular signal loss and therefore greater apparent narrowing of the lumen than with the 3D technique. In the case of a severe stenosis, there is frequently a flow void or complete absence of signal in the involved segment so the morphology of the stenosis cannot be defined at all. The reader simply concludes that the vessel is severely stenotic because there is complete loss of signal in that segment with reappearance of the vessel distally. Whereas the MRA images agreed with the catheter studies in up to 75% of cases, overestimation of the stenosis was seen in up to 44%.^{24,25} As expected, the highest percentage of these errors was evident in those studies with relatively long echo times and large voxel dimensions. The most significant error, however, was seen in those cases of moderate stenoses which were labeled as 'severe' on MRA. This was a problem even with a slice thickness of 1.5 mm and echo times of approximately 9.0 ms.²⁴ If MRA is used as the sole imaging study preoperatively, a carotid endarterectomy may be recommended inappropriately. It can be argued that Doppler ultrasound could be performed in conjunction with the MRA, but the ultrasound also has potential pitfalls such as operator dependence, machine variability, vessel tortuosity and plaque calcification leading to nondiagnostic studies, overestimation of stenoses, and (although less commonly with color flow systems) misdiagnoses of complete occlusion at the bifurcation.

Although it is difficult to depict the morphology of severe stenoses, the sensitivity of the 2D TOF technique to slow flow generally makes it readily able to distinguish a severe stenosis from an occlusion if the slice thickness is sufficiently small, the *TR* is sufficiently long, and a long enough segment of the vessel is evaluated to include a segment in which the flow has returned to a laminar profile.²² Nevertheless, in a few cases, MRA overestimates a critical stenosis as an occlusion which has important clinical implications as the patient is no longer considered a surgical candidate if the vessel is occluded.

The 2D TOF studies have also been compared to Doppler ultrasound examinations of the carotid bifurcations. The only noticeable difference was that the MRA studies tended to be less likely to misdiagnose a severe stenosis as an occlusion, but there was ultimately no statistically significant difference in accuracy between the two modalities.^{24,26} Both studies tended to overestimate the degree of carotid stenosis. Even when the

results of the two examinations are in agreement, they still do not necessarily correlate with the invasive arteriogram and may not have the accuracy to replace the conventional study.^{24–26}

Other groups have primarily relied upon 3D TOF imaging in patient studies because of a lesser degree of flow-related dephasing and, consequently, improved characterization of carotid stenoses. When single-volume 3D TOF MRA was compared to intra-arterial digital subtraction angiography (IADSA) using a caliper technique, ROC analysis showed that technically adequate 3D TOF MRA images can be interpreted consistently, show a very strong correlation with IADSA, and that 3D TOF MRA may be a sensitive screening examination for extracranial carotid stenoses.²⁷ In spite of the advantages of the 3D sequence parameters, the more severe stenoses may still be accentuated due to higher order motion in the region of the stenosis. As alluded to above, another obvious limitation of the 3D technique is its potential to misrepresent a severe stenosis as an occlusion so 2D and 3D TOF carotid MRA investigations have been combined in patient examinations to avoid this pitfall.²⁸

Even when the 2D and 3D TOF studies are combined, it seems unlikely at this time that MRA, duplex ultrasound, or the combination of the two can replace conventional angiography in patients who are being considered for surgery. It would be more appropriate for these modalities to serve as a screening examination, and, if a significant stenosis is detected, an invasive diagnostic study can be performed for further evaluation prior to surgical intervention. Based on the guidelines set by the NASCET study, it is now not only necessary to measure accurately the luminal narrowing but it is also necessary to exclude the presence of a tandem stenosis elsewhere in the carotid circulation.⁶ Moreover, it is important to measure the stenosis in a consistent fashion and to have the capability to distinguish different gradations of severe luminal compromise since the NASCET study demonstrated a greater benefit of the endarterectomies with increasing severity of the stenoses. While the 3D TOF technique characterizes the morphology of the stenotic segment more accurately than 2D studies, both tend to exaggerate the degree of narrowing and may show complete signal void within the stenosis (particularly in the 2D studies) (Figure 1).

Further improvements should be realized with improved gradient capabilities which will permit shorter echo times, higher resolution, and reduced intravoxel dephasing at the site of severe stenoses.^{18,29}

1.5 Carotid MRA: Clinical Applications—Carotid Dissection

Dissection of the carotid artery is not an infrequent cause of stroke but tends to occur in younger adults than strokes relating to atherosclerotic disease. If the clinical suspicion is low, a carotid dissection is only one possible explanation for the patient's clinical presentation, and/or there is a relative contraindication to conventional angiography. MRI in conjunction with MRA serves as a noninvasive alternative to evaluate for dissection and to identify simultaneously the extent of parenchymal sequelae. Catheter angiography, however, remains the gold standard, and is the most reliable means by which the underlying etiology can be identified (e.g. fibromuscular dysplasia). The conventional study may also be the only method

Figure 1 (a) Stacked overlapping volume acquisition of the carotid bifurcations shows no significant saturation despite the tortuosity of the vessels and the proximal stenosis of the internal carotid artery. (b) The degree of stenosis (arrow) is less severe in the conventional arteriogram, likely due to the long gradient duration for the MRA acquisition

of fully appreciating the extent of collateral filling of the intracranial circulation if the alternative routes are circuitous with slow flow in small vessels. Alternatively, it is also possible to have a false-negative catheter study if the vessel is completely occluded (nonfilling) or the dissection is subadventitial (normal size and configuration of the lumen) and the MRI/MRA study may be the best way to confirm the diagnosis by demonstrating the periluminal blood products.³⁰ In routine T_1 - and T_2 -weighted spin echo imaging the dissection is generally detected as a crescentic area of hyperintensity around a narrowed lumen of the cervical internal carotid artery.³¹ In particular, an axial T_1 -weighted spin echo study using fat saturation and an inferior spatial saturation pulse suppresses the signal of the perivascular fat and intraluminal flow-related enhancement, thereby increasing the conspicuity of the hyperintense (short T_1) periluminal hemorrhage.³²

MRA is used to complement conventional spin echo imaging in the evaluation of patients with suspected carotid dissections.³³ As in IADSA studies, the internal carotid artery may appear narrowed and there may be poor flow-related enhancement proximally if the outflow through the internal carotid artery is severely impaired. The dissection is often imaged when the periluminal hemorrhage contains methemoglobin, so the vessel lumen can appear artifactually widened on the MRA since the hyperintense thrombus is similar in intensity to the

flow-related enhancement in the true lumen. Because of the variability in the state of evolution of the thrombus, the hemorrhagic by-products are either hyperintense or hypointense relative to the lumen. If the distinction between lumen and hemorrhage is not apparent on the projection arteriogram images, the two lumena and the intervening flap are usually evident in the source images for the MRA.

1.6 Intracranial MRA: Technical Considerations

The intracranial circulation presents problems similar to those seen in the evaluation of the extracranial cerebral vasculature except the studies are further complicated by smaller vessels, field inhomogeneities, and reduced through-plane flow. The 3D sequences seem particularly well suited to this situation as they not only provide the high spatial resolution needed to visualize the smaller vessels but they also provide the reconstruction capabilities (maximum intensity projection) necessary to display the complex intracranial vascular geometry. Intracranially, local field inhomogeneities exist at air-soft tissue and bone-soft tissue interfaces while higher order motion terms occur at focal vessel tortuosities, bifurcations, and luminal stenoses. Both of those factors are limited by small voxels and short echo times. In comparison to the 2D sequences, the 3D acquisitions are better able to demonstrate the large component

of in-plane flow intracranially (with appropriate adjustments in the *TR* and flip angle to avoid saturation).

The reduced flow velocities and large component of in-plane flow are still somewhat limiting in the 3D acquisitions as these factors aggravate the problem of spin saturation, thereby reducing the vessel–soft tissue contrast particularly in the distal volume. Adjustments in the conventional imaging parameters provide only limited benefit. The incorporation of magnetization transfer saturation in all intracranial TOF MRA studies has become routine.³⁴ Since the off-resonance saturation pulse suppresses the signal of the bound water molecules, and the bound component is largely restricted to the brain parenchyma, the magnetization transfer saturation effectively enhances the vessel–soft tissue contrast. Additional vascular contrast may be obtained by incorporating the spatially varying rf pulses for excitation designed to limit the problem of spin saturation. Because of the slower flow rates in the intracranial arteries, the most promising TOF technique seems to be the stacked volume approach, which combines the advantages of 2D and 3D TOF acquisitions.²¹

Phase contrast sequences are also commonly used to evaluate the intracranial circulation. The vessel geometry and small size of the arteries make the 3D acquisition necessary for most purposes but, for comparable spatial resolution and flow sensitization along all three planes, the acquisition time is longer and the postprocessing more complex for the 3D PC technique. Alternatively, 2D acquisitions may provide similar flow information relatively quickly, but at the expense of limited anatomical coverage. A problem common to both phase contrast techniques is the need for some a priori knowledge of the range of velocities present within a given patient or lesion. Inappropriate choice of the velocity-encoding gradient can cause poor visualization of the small and/or peripheral vessels with slow flow if the chosen velocity-encoding gradient is too weak, or aliasing of flow information and signal loss if the chosen velocity range is too low. On the other hand, the freedom to choose different velocity encodings provides options that are not possible or more cumbersome in a TOF acquisition such as the direction of blood flow (e.g. collateral flow in the circle of Willis).^{35,36} Alternatively, directional information is easily attainable in the PC acquisition without performing a separate study. The PC studies also readily provide the capability to measure flow velocities and volume flow rates of individual vessels. Lastly, if 2D PC studies are performed in a cardiac gated cine mode, the flow dynamics in various vascular lesions can be studied at different, specified velocity ranges which is only possible in a very limited fashion with TOF techniques.

1.6.1 Intracranial MRA: Aneurysms

The statistics relative to subarachnoid hemorrhage from a ruptured intracranial aneurysm remain devastating—greater than 50% mortality and major morbidity.³⁷ Given the low operative morbidity and mortality of surgery on unruptured aneurysms, it is appealing to consider the possibility of using MRA as a screening test. It would be especially applicable in patient groups where there is an increased incidence or a high anxiety level for an aneurysm, such as patients with a strong family history, polycystic kidney disease, aortic coarctation, fibromuscular disease, and collagen vascular disease. Based on the decision analysis of Levy et al., the risk of an aneurysm

even in these groups does not warrant the screening of all these patients with conventional arteriography.³⁸ It is possible, however, to perform an accurate noninvasive pretest that would increase the prevalence in subgroups which could then be studied by conventional arteriography for further evaluation. Based on the results of MRA in the evaluation of intracranial aneurysms, MRA exceeds the criteria of sensitivity and specificity for the noninvasive pretest outlined by Levy et al.^{37,39} It is possible to use high resolution contrast enhanced computerized tomography (CT) to study these patients, but the sensitivity and specificity have not been studied, and the requirement of intravenous iodinated contrast and the beam hardening artifact from the skull base are potentially limiting, which make MRA preferable.⁴⁰ Currently, TOF MRA is frequently used as a screening test in these groups or in stable patients with a subacute onset of symptoms in which an intracranial aneurysm is only one of a number of potential explanations for the clinical presentation and the suspicion of an aneurysm is not high enough to warrant a conventional arteriogram (Figure 2). However, the patients who present acutely with a subarachnoid hemorrhage are best served by a nonenhanced head CT followed by conventional catheter angiography.

Retrospective studies have been conducted to test the accuracy of the 3D TOF MRA method for the detection of intracranial aneurysms as compared to IADSA examinations.^{39,41,42} Aneurysms as small as 3–4 mm have been detected using 3D TOF and 3D PC techniques. In a series of 21 angiographically confirmed aneurysms in 19 patients, the authors demonstrated an increase in sensitivity from 67% when evaluating the 3D TOF MRA projection images alone, to 86% when the MRA arteriogram images were evaluated along with the source images from the 3D data set and the spin echo images. Using the MIP images, the individual slices, and the spin echo study, the sensitivity was calculated to be 95% for the detection of at least one aneurysm in a patient such that the study would lead to the referral for a conventional arteriogram for further evaluation preoperatively.

Recognizing the limitations of these MRA acquisitions becomes particularly important when choosing the method of postprocessing, interpreting the images, and recommending a conventional arteriogram as a follow-up study or in place of MRA. Larger aneurysms or aneurysms compressing the parent vessel may reduce the extent of inflow and washout of fresh unsaturated spins within the aneurysm lumen, which causes an apparent reduction of the size of the aneurysm on TOF studies.⁴¹ This is less of a problem with a PC acquisition if the preliminary spin echo study reveals a giant intracranial aneurysm, so that a low velocity encoding range can be selected for PC MRA.⁴² On the other hand, these lesions are also obvious on the spin echo study owing to the prominent flow artifacts, intimate relationship with the adjacent basilar vessels, and (if present) the contained blood products.

The stagnant flow within a large aneurysm tends to promote thrombus formation which partially fills the aneurysm lumen. Since the TOF sequences are inherently T_1 and spin density weighted, both the thrombus and the patent lumen may be visible on the MIP images, depending on the state of evolution of the thrombus just as in conventional IADSA. This will cause an underestimation of the overall aneurysm size in PC studies because of the strong background suppression. In the case of

subarachnoid hemorrhage, the aneurysm and the parent vessel may not be observed altogether.

Although the gross relationships with the parent vessel may be visible, identification of the aneurysm neck may be difficult at times when evaluating the projection images and occasionally with conventional cerebral angiography. In these cases, evaluation of the 3D TOF source images and multiplanar reconstructions of the original slices create 'angiotomograms' to delineate more clearly both the aneurysm and its point of origin. Alternatively, reconstructing vessels from small subvolumes that contain only the vessels of interest provides images with better definition (reduces the artifact inherent to the MIP algorithm) and eliminates the problems relating to vessel overlap.⁵ This is especially helpful with aneurysms arising from a tortuous carotid siphon or in determining which branch the aneurysm arises from if it occurs at a bifurcation (e.g. middle cerebral artery bifurcation/trifurcation). More importantly, routine evaluation of the source images and planar reconstructions of the axial slices reduces the likelihood of missing small aneurysms that may otherwise be missed by reviewing only the projection MRA images.

Identifying the relationship of the aneurysm to the parent vessel may also be difficult if the aneurysm arises from an arterial segment that is incompletely visualized due to motion induced dephasing. This is most commonly seen in the carotid siphon, particularly if the supraclinoid segment is immediately apposed to the juxtasegmental segment so the turn of the siphon is rather tight. Because of a greater tendency towards motion induced dephasing, this should be more problematic with PC than TOF acquisitions. Shorter gradient times and smaller voxels significantly reduce the phase dispersion and signal loss in these vessels.¹⁹⁻²¹

MRA can also be applied to the long term postoperative follow-up of aneurysm patients treated via an endovascular route (e.g. balloon occlusion) or noninvasive follow-up of a known, untreated aneurysm (Figure 2). Susceptibility artifacts from the nonferromagnetic aneurysm clips preclude the evaluation of aneurysms treated by surgical clipping but would not prohibit the use of MRA to evaluate for intracranial aneurysms elsewhere.

1.6.2 Intracranial MRA: Arterial Occlusive Disease

Patients with symptoms of cerebral ischemia are frequently examined by MRI to assess the extent of parenchymal ischemic disease. The morphology and signal characteristics of the vessel lumina can only suggest stenosis and slow flow or occlusion, whereas MRA can directly identify the site and severity of the underlying stenosis. Not infrequently, the patient has already had a Doppler ultrasound study of the carotid bifurcations, and the ischemic symptoms are not explained by the mild narrowing in the carotid bifurcations. MRA provides an additional noninvasive study which can be performed at the same time as the spin echo study to evaluate the morphology of the intracranial vessels. Alternatively, in a patient with severe stenosis, MRA provides the means by which the physician can evaluate the degree of collateral flow to the circulation that is severely compromised in the extracranial circulation. As compared with transcranial Doppler ultrasound studies, MRA is better able to evaluate the posterior fossa circulation and provides an anatomical display of the intracranial vasculature that is not possible with the transcranial Doppler technique.^{43,44} The MRA findings can alert the clinician to the nature and location of the occlusive disease and a conventional

Figure 2 (a) This 55-year-old woman is known to have a basilar tip aneurysm and is presenting for noninvasive follow-up. The aneurysm is seen as a rounded hypointense focus (arrow) in the interpuncular cistern. (b) The 3D TOF MRA image confirms the aneurysms (arrow), including its size and orientation with respect to the parent vessel

angiographic study could then be performed to confirm the full extent of pathology prior to starting therapy if the MR/MRA findings do not explain the clinical situation or if surgical or endovascular therapy is being considered. Alternatively, a negative study might avert the need for an invasive diagnostic examination altogether. The hope for the future is that MRA can effectively evaluate for tandem stenoses in the distal internal carotid arteries in patients being considered for carotid endarterectomies and, in combination with a similar noninvasive study of the carotid bifurcations, can obviate the need for an invasive study preoperatively (i.e. noninvasively meet the NASCET criteria).

Initial studies have been restricted to the evaluation of the larger vessels such as the carotid siphon, the proximal anterior and middle cerebral arteries, the distal vertebral arteries, and the basilar trunk. This is, in part, related to the spatial resolution limitations of these sequences and the small vessel caliber of the intracranial vasculature. Narrowing of the distal peripheral vessels, typical of cerebral vasculitis, cannot be effectively evaluated with MRA, and requires a conventional arteriogram. Flow rates also impose restrictions in the TOF acquisitions as only the larger arteries of the circle of Willis will have flow which is rapid enough that the flow-related enhancement will likely 'opacify' the vessel distal to the stenosis. This is not as problematic with the PC sequences if the physician has a priori knowledge about the expected range of flow velocities in the vessels.

3D TOF MRA is readily able to display normal vessels and to distinguish normal from stenotic vessels. In one study, the sensitivity for identifying stenoses in the distal vertebral and basilar arteries was shown to be 100% whereas the specificity of the study was not nearly as high.⁴⁴ When 3D TOF MRA was compared with the IADSA studies, the degree of stenosis was exaggerated in as many as 63% of the MRA images. When correlated with the results of other clinical studies, this error was likely accentuated to some extent by the chosen voxel dimensions, the small but highly variable caliber of the distal vertebral arteries, and the separation of the stenoses into five categories.⁴⁴ Reviewing the original 3D source images was found to be helpful for distinguishing occlusion from slow flow in a severely stenotic or hypoplastic vessel. This distinction was further aided by incorporating selected 2D TOF slices because of their improved sensitivity to slow flow.

Knowledge of the degree of collateral flow between different vascular territories may have a significant impact on the physician's therapeutic decisions. Often times, the method of cross filling is obvious on the standard TOF MRA acquisition. For example, if one internal carotid artery is occluded but there is still good flow to the corresponding anterior circulation, the flow is more likely through the patient's large anterior communicating artery than the diminutive posterior communicating arteries. It is not as easy to draw these conclusions when the potential collateral vessels are more uniform in size or they are all diminutive. The slow flow and small size of leptomeningeal collateral vessels prevents their visualization. Evaluation of the source images from PC studies clearly demonstrates the direction of flow in major vascular trunks, making the pattern of collateral flow obvious.³⁶ Moreover, PC studies also provide the potential to make flow velocity and flow volume measurements. Alternatively, examining the corresponding phase images from a TOF study can also confirm the direction of

blood flow in main vascular trunks. The relative contributions from the other vascular territories can also be identified in a TOF study through the use of appropriately positioned saturation pulses.³⁵ A narrow saturation slab, which is perpendicular to a 2D TOF slice or narrow 3D TOF volume, can be oriented to eliminate the flow-related enhancement from any one or any combination of the main vascular trunks to identify the source of collateral flow to a given vascular distribution. For example, selectively saturating the contralateral internal carotid artery will demonstrate the relative contribution from the posterior circulation to the remaining internal carotid artery distribution in question.

1.6.3 Intracranial MRA: Vascular Malformations

Intracranial vascular malformations are generally easy to identify on the routine spin echo study of the head. Capillary telangiectasias are usually discovered incidentally at autopsy while cavernous angiomas are most commonly detected as subcortical foci of mottled hyperintensity on the T_1 - and T_2 -weighted sequences with a peripheral rim of ferritin and hemosiderin deposition on the T_2 images from prior hemorrhage.⁴⁵ In both cases, the flow through these lesions is so slow that their abnormal vessels cannot be visualized by any MRA technique. (In fact, TOF MRA images can be misleading since the short T_1 of hemorrhage in a cavernous angioma can mimic the high flow vascular nidus of an arteriovenous malformation.) Venous angiomas are also readily identified on the spin echo study as a caput of veins draining into a large medullary vein extending from a point near the ependymal surface to the cortex. While the sensitivity to slow flow in the 2D TOF or PC studies would make these veins visible with MRA, their characteristic spin echo appearance makes this unnecessary.

High flow arteriovenous malformations are also easily diagnosed on the conventional spin echo parenchymal study. The vascular nidus appears as a cluster of serpiginous flow voids because of the relatively fast flow through these vessels. The factors that are considered important predictors of surgical resectability are also readily appreciated, including the size of the nidus, its relationship to eloquent areas of the brain, and the presence of deep venous drainage.⁴⁶ If there is a direct arteriovenous fistula, there will be no intervening nidus but the enlarged feeding arteries and draining veins will still be easily identified. There may also be associated parenchymal findings related to hemorrhage, ischemic steal, secondary venous thrombosis, or prior surgical, embolization and/or radiation therapy. The arteriovenous malformations can be identified with TOF or PC MRA, but the images generally do little more than reinforce the 3D spatial relationships of the vascular nidus with the circle of Willis and identify the main feeding arteries and draining veins.

Conversely, one situation in which MRA is essential in the work-up is in the evaluation of suspected dural vascular malformations which make up approximately 15% of the arteriovenous malformations. Frequently, the dural malformations are not visible at all on the spin echo study because of the small size and lack of contrast between the flow voids and the adjacent hypointense skull base.⁴⁷ The only clues to the presence of the malformation may be the clinical history, the presence of enlarged draining cortical veins, or secondary findings such as dural venous thrombosis, subdural or parenchymal

hematomas, and venous infarcts. On occasion, subtle peripheral flow voids or focal prominence of a dural venous sinus may be present, but these are often identified only in retrospect, once the MRA study makes the diagnosis obvious. MRA is often able to identify the vascular nidus along the dura, enlarged branches of the external carotid and/or vertebral arteries, and possibly enlarged draining veins or dural sinuses if there is a direct arteriovenous fistula present. It is essential to evaluate the source images from the MRA acquisition, as the findings may even be subtle on the projection MRA. Intravenous gadolinium can be used with 3D TOF MRA to evaluate better small feeding arteries and draining veins, but a study of dural fistulas failed to identify venous constriction. A study of dural fistulas with 3D TOF MRA was unable to identify venous constriction when gadolinium was used to reduce the problems of spin saturation and better identify the slow flow in the small feeding arteries and draining veins.⁴⁸

Ultimately, conventional catheter angiography will be performed on any patient with an arteriovenous malformation to characterize it prior to therapy. Only the invasive arteriogram provides the spatial resolution necessary to identify all of the afferent and efferent vessels. While the MRA acquisition can identify aneurysms along the afferent vessels, these too should be further evaluated by a conventional arteriogram preoperatively. Lastly, only the catheter study provides the temporal resolution to assess the arteriovenous circulation time, to identify individual vessels with the greatest degree of arteriovenous shunting and, in the case of a direct fistula, to localize the point of communication between the arterial and venous systems.

The MRA acquisitions can be designed to provide a limited degree of physiological information about the vascular malformations. Thin saturation slabs can be applied to a 2D or thin volume 3D TOF acquisition to eliminate the flow-related enhancement from one vascular trunk and monitor the relative intensity and/or size of the malformation in the final image. In this way, it is possible to determine if the malformation is fed by more than one vascular distribution (collateral flow) and to assess the relative contributions from the different vascular territories.³⁵ The PC acquisitions can also be designed to supply similar information by applying a series of different velocity-encoding gradients in a stepwise fashion to demonstrate different components of the malformation.³⁵ A low velocity-encoding range (e.g. 10–20 cm s⁻¹) would demonstrate draining veins with low to medium velocities whereas higher velocity-encoding ranges (e.g. 60–100 cm s⁻¹) would preferentially demonstrate the nidus, larger veins, and feeding arteries with more rapid flow.⁴² In this fashion, it is possible to provide a velocity flow map of the vascular malformation. Such information may be clinically useful if serial studies indicate a change in flow dynamics which may be predictive of hemorrhage, but this remains to be tested.

In spite of the advantages, saturation of flowing spins is perhaps the most significant limitation of the 3D TOF technique. This limits visualization of the small feeding arteries (slower flow) distally in the volume, all but the largest early draining veins, and potentially part of the vascular nidus itself if there is relatively slow flow through the nidus and it is located distally in the volume. The 2D TOF studies are less susceptible to spin saturation and provide better contrast-to-noise levels across the imaging volume. Alternatively, 2D TOF images are more lim-

ited by flow-induced dephasing and may not visualize portions of the afferent and efferent vessels depending on the direction along which the slices are acquired relative to the course of these vessels. The problem of spin saturation is reduced with intravenous gadolinium, but this also increases the intensity of the background tissues, which may be quite limiting if the malformation is situated along the skull base (e.g. many dural vascular malformations). The best compromise between the TOF techniques is the stacked overlapping volume approach.²¹ If the malformation is located within the parenchyma, a paramagnetic contrast medium could be added to improve venous visualization, while the stacked volume approach improves arterial visualization.⁴⁹

1.6.4 Intracranial MRA: Venous Sinus Thrombosis/Occlusion

Dural venous sinus thrombosis and secondary parenchymal findings (e.g. edema, hemorrhagic venous infarct) can be detected on conventional spin echo images although the findings are not always obvious and may be misleading. The most sensitive spin echo study to evaluate the venous sinuses is a T_2 weighted sequence in which the slices are oriented perpendicular to the direction of flow in the sinus in question (e.g. coronal for the superior sagittal and straight sinuses). With such a long echo time, blood flowing perpendicular to the slice normally causes a flow void as it is least apt to experience the 90 and 180° pulses and remain in the imaging plane at readout unless the sinus is thrombosed or occluded. An occluded sinus will fail to demonstrate a flow void or may be frankly hyperintense on the T_1 - and T_2 -weighted images. Slow flow may also cause an intermediate to high signal within the sinus and simulate thrombus. In the case of acute/early subacute thrombus, the hypointense thrombus may simulate a flow void on a T_2 -weighted image.⁵⁰ In the situations where the spin echo findings of thrombosis are ambiguous or an adjacent mass appears to have invaded and occluded the sinus, MRA venograms can be most helpful in confirming or excluding thrombosis/occlusion without resorting to an invasive study.

A 2D technique would be the most sensitive TOF study to evaluate the slow flow in the dural sinuses.⁵¹ Coronal slices acquired sequentially, from posterior to anterior, should ensure flow-related enhancement in the major dural sinuses since the flow is largely in the reverse direction except the posterior portion of the superior sagittal sinus. This same strategy can be followed with fewer slices and a shorter examination time if the slices were acquired in an oblique coronal plane (e.g. rotated 75° towards the sagittal plane). In view of the relatively slow normal velocities in these veins, the slice thickness for these 2D slices should be minimized, the TR maintained relatively long, and a low-to-intermediate flip angle should be used (e.g. 30°) to avoid spin saturation. Hyperintense thrombus could simulate flow-related enhancement, but this is easily distinguished when correlated with the findings on the spin echo study. The prior administration of intravenous gadolinium would make it difficult to distinguish a normal sinus from contrast enhancement along the periphery of a thrombosed sinus. A more important potential error relates to the limitations of the technique. There may be insufficient flow-related enhancement in a small sinus with slow flow, leading to a false-positive study. Similarly, an oblique coronal acquisition will insure flow-related enhancement in one transverse sinus, but

this is not necessarily the case in the opposite transverse sinus. In either case, evaluating the individual slices or reconstructing a small subvolume eliminates the reconstruction artifact and usually makes it possible to distinguish patency from occlusion.

Phase contrast techniques are especially well suited to this application because of strong background suppression and the ability to adjust the sequence so it is sensitive to very slow flow ($10\text{--}20\text{ cm s}^{-1}$).^{52,53} While the sensitivity of the 2D TOF study is sufficient for most routine clinical work, the sensitivity is somewhat greater with PC, and it may be possible to detect flow in a recanalized sinus when the TOF images would suggest occlusion. The relatively large size of these sinuses, laminar flow profiles, and predominantly unidirectional flow make it easy to study these veins with two quick 2D PC acquisitions. A thick 2D slab can be selected in the midline sagittal plane, with velocity sensitization along the anterior/posterior direction, to assess the patency of the deep and superficial midline veins. A second thick axial slab in the posterior fossa with sensitization in a similar direction will evaluate the patency of the transverse and sigmoid sinuses.

1 INTRODUCTION

While conventional angiography has been the 'gold standard' in the evaluation of peripheral vascular disease, recent technical advances have made magnetic resonance angiography (MRA) a favorable alternative in many instances. Multiplanar imaging capabilities and noninvasive acquisition of data provide distinct advantages over contrast angiography. Overnight hospital stays, and potential morbidity from contrast injection and from obtaining arterial access may be avoided with MRA. Furthermore, distal runoff may be obscured by inadequate contrast filling in up to 70% of cases.¹⁻⁴ This has mainly been attributed to contrast dilution in intramuscular collaterals before reaching the reconstituted vessels of interest. MRA allows cross-sectional imaging, which facilitates the evaluation of the vessel lumen for stenotic lesions. Impaired detection of stenotic lesions due to interference from overlying bone is not a problem, although it may be in contrast angiography. Quantitation of flow, in particular by cine-phase contrast, is also possible with MRA. Three-dimensional data sets may be obtained by MRA. Gravimetric layering of contrast, which may prevent filling in anterior branches of slow-flowing vessels, is obviated with MRA. Pulsatility artifacts tend not to be a problem in studying collateral reconstitution past a high level stenotic lesion, since these vessels often adopt a monophasic rather than a triphasic wave pattern. However, with the advent of digital subtraction angiography, a higher level of technical proficiency and accuracy can be achieved. Inplane resolution is superior with cut-film angiography compared with MRA. Skeletal bony anatomy, sequential demonstration of retrograde flow, metal artifacts, and total length of vascular anatomy, may be better appreciated with contrast angiography. Also, contraindications to MR, such as pacemakers, defibrillators, and metallic prosthetic valves, prohibit its use in these instances.

Various artifacts of MRA will be discussed later in further detail. Bearing all this in mind, MRA may play an integral part in the presurgical evaluation of lower-extremity ischemia by providing the surgeon with the arterial anatomy in a noninvasive manner. It may afford decreased intraoperative times. Stenosis, occlusions, and native target outflow vessels favorable for bypass procedures may be identified noninvasively. In addition, reconstituted vessels may potentially be seen to better advantage.

2 TECHNIQUES

Currently, the predominant technique for imaging the peripheral vasculature consists of two-dimensional (2D) time-of-flight (TOF). Single sections are imaged perpendicular to the plane of flow. Short *TR* is utilized to saturate stationary spins, which imparts high intensity to flowing blood where spins are unsaturated. This flow-related enhancement allows visualization of the peripheral vasculature [Figure 1(a)]. Further selection of the arterial or venous system can be accomplished by utilizing a saturation band [Figure 1(b)].

A saturation band positioned distally to the imaging section would provide an arterial study. This relationship would be reversed in the head and neck, where venous blood generally travels inferiorly rather than superiorly and arterial blood courses superiorly rather than inferiorly. During arterial diastole, there is a component of flow reversal which allows arterial blood to enter the presaturation slab during systole and subsequently the imaging section during diastolic reversal of flow if the slab is positioned close enough to the imaging section. This creates undesirable dark, horizontal, stripe artifacts. For this reason, a saturation gap is often utilized. A saturation gap is a distance placed between the saturation pulse and the

Figure 1 Single slice from a 2D TOF angiogram taken: (a) without saturation bands demonstrating both arteries (larger arrows) and veins (smaller arrows); (b) with inferior saturation. The venous structures have been saturated out and only arterial structures remain

Figure 2 MIP projection obtained from a 2D TOF arteriogram in the region of the calf, demonstrating high-signal arterial vessels (large arrow) and lower signal venous vessels (small arrow). The veins are visible due to the wide saturation gap (2 cm) used in this case

imaging plane. The larger the gap, the less likely that retrograde arterial flow from the saturation slab will reach the imaging section. On the other hand, a larger gap would also enable venous blood within the gap to enter the imaging slice without first being saturated. Therefore, some venous blood may also be inadvertently imaged and potentially confused for arterial flow. This phenomenon is called ‘venous bleed-through’ (Figure 2). It is therefore evident that the size of the saturation gap is critical and that the optimal saturation gap size may vary depending upon the arterial and venous flow rates at the particular site of interest. In addition to the above techniques, we also utilize flow compensation at our institution.

The 2D axial images obtained are stacked on top of each other to create a three-dimensional (3D) data set. Projection angiograms are created by the MIP algorithm. A ray is projected through this 3D data set, and each pixel in the projection is designated a value based on the maximum intensity encountered within the pixel.

At our institution, we utilize a *TR* of 33–36 ms, a *TE* of 6.2–7.7 ms, and a 60° flip angle. Our 2D TOF imaging protocol entails imaging at several stations. The pelvis is imaged with a 32 cm field-of-view (FOV), 2.5 mm thickness, 128 × 256 matrix, and a body coil. No skip is utilized. Distal thigh, knee, leg, ankle, and foot are imaged with an extremity coil at a 16 cm field of view. Ninety 2 mm images per station are obtained with the knee coil. The pelvis and one lower extremity are imaged in approximately 1.5 h. Station 1 is at the forefoot, where the dorsal and plantar arches form from the dorsalis pedis and posterior tibial arteries [Figure 3(a)]. Upper and lower margins of the coil are marked to ensure that all vessels are examined, which in the General Electric knee coil is up to 20 cm long. In patients with peripheral vascular disease, the flow distally tends to be nonpulsatile, thus a

narrower saturation gap is utilized. This also limits venous bleed-through. The arches frequently cannot be seen, since they course horizontally and become saturated. Retrograde flow, sometimes seen in the dorsalis pedis, susceptible to saturation by the inferior saturation slab, may create the impression of stenosis on the MIP.

The second station examines the anterior tibial, posterior tibial, and peroneal arteries [Figure 3(b)]. Calcaneal and perforator branches arise from the peroneal artery, and these course posteriorly and anteriorly, respectively. The calcaneal artery (communicator branch) may function as a collateral to the plantar aspect of the foot, while the perforator branch coursing through the interosseous membrane may function as a dorsal collateral. The posterior tibial artery bifurcates into medial and lateral plantar arteries at the ankle.

The third station ends at the mid-calf [Figure 3(c)]. The posterior tibial artery is most medial and usually anterior to the peroneal artery. The anterior tibial artery is located very superficially at the talus, where the dorsalis pedis forms, and it travels in the tibialis anterior muscle within the anterior compartment. The peroneal artery parallels the fibula. Intramuscular collaterals may accompany disease at the trifurcation. Venous bleed-through may mimic such arterial collaterals.

The fourth station, at the knee, is where the popliteal artery and the trifurcation are evaluated [Figure 3(d)]. Basis images are critical, especially for assessing stenosis of the anterior tibial artery. This area represents the most variable for the number of vessels seen. Anatomic variation, occlusion, and collaterals all contribute to this phenomenon. The length of the region examined is also variable due to individual height discrepancies.

The fifth station examines the common femoral artery to the superficial femoral artery (SFA)–popliteal artery junction [Figure 3(e)]. The SFA is medial and superficial. The profunda femoral artery is posterior and lateral in location, and terminates at the mid-thigh with associated muscular branches. The SFA has no muscular branches. Hunter’s canal is contained in this series. Stenoses at this level are common. Faster arterial inflow and venous outflow at this station are conducive to a shorter *TR* (33 ms) and a larger saturation gap (1 cm), respectively.

The sixth station (pelvis) covers the distal abdominal aorta to the common femoral arteries [Figure 3(f)]. The aorta normally bifurcates into the common iliac arteries, which further bifurcate into internal and external iliac arteries. The common femoral arteries subsequently give rise to the deep and superficial femoral arteries. The faster flowing veins at this level require an even larger saturation gap (2 cm) at this station.

3 CLINICAL DATA

Clinical data thus far has shown 2D TOF MRA to be a promising technique. Mulligan et al. studied 140 lesions and found a 71% correlation between 2D TOF MRA and conventional angiography of the abdominal aorta and distal-runoff vessels.⁵ MRA alone proved inaccurate in six out of 140 cases for planning a surgical approach. As this was one of the early studies in this area, these inaccuracies to some extent may reflect inadequacies of the early techniques. Later studies by other investigators produced more promising results, probably

Figure 3 Two-dimensional TOF projection: (a) through the hind foot, demonstrating the dorsalis pedis artery dorsally; (b) anteriorly through the ankle. The anterior tibial (small arrow), peroneal (curved arrow), and posterior tibial arteries (large arrow) are demonstrated; (c) anteriorly in the region of the mid-calf, demonstrating the anterior tibial artery (small arrow) and tibial peroneal trunk bifurcating into posterior tibial (large arrow) and peroneal arteries (curved arrow); (d) through the region of the knee, demonstrating the popliteal artery and the take-off of the anterior tibial artery (arrow); (e) obtained with the body coil, demonstrating the superficial femoral arteries bilaterally from upper thigh through Hunter's canal (large arrows). The distal profunda femoral arteries are also identified (small arrows); (f) through the pelvis, demonstrating the aorta, common iliac arteries (largest arrows), internal (small curved arrows) and external iliac (larger curved arrows) arteries, and common deep (curved open arrow) and superficial (open arrow) femoral arteries. Note the excellent visualization of the femoral artery bifurcation

Figure 4 Representative images from the magnetic resonance arteriogram of a patient who presents with lymph-threatening ischemia. (a) Images through the pelvis demonstrating bilateral iliac artery occlusion and reconstruction of the SFA bilaterally (arrows). (b) Images obtained through the upper thighs. Bilateral superficial femoral artery occlusions are demonstrated (arrows). (c) Images through the lower left calf. The presence of an anterior tibial artery crossing the ankle to form the dorsalis pedis (arrow) and a peroneal artery (curved arrow) with a calcaneal branch crossing the ankle to form the plantar arches is demonstrated. On the basis of these MR images, this patient went on to have revascularization procedure without contrast angiogram

due to technical advancements. Color-duplex ultrasound (US) demonstrated 93% concurrence for infrainguinal disease. While MRA was superior to US in evaluating the iliac regions due to limited visualization with US in that area, image quality with MRA was inconsistent. Workers concluded that both duplex US and MRA were suboptimal for surgical planning. Owen et al. found that most of the discordance between 2D TOF MRA and conventional angiography was due to enhanced detection of runoff vessels on MRA⁶ (Figure 4). Interventional planning was altered in 16% of cases (12 patients) due to improved visualization with MRA of stenosis and vessels not seen on conventional angiography.

Carpenter et al. studied 51 patients with peripheral vascular disease.⁷ Two-dimensional TOF MRA evaluation demonstrated that in 48% of cases, MRA provided additional information to

contrast angiography without loss of other information. In 22% of cases, the MRA data were responsible for altering surgical treatment. Target vessels were observed in 18% of cases on MRA that were undetected on contrast angiography. Identification of these target vessels enabled the surgeons to perform limb-salvaging procedures. Similarly, two cases (4%) demonstrated MRA findings of target runoff vessels which were not seen on conventional angiography, where the information was used to formulate a better interventional plan for bypass grafting. These investigators demonstrated superior sensitivity of MRA compared with contrast angiography in evaluating distal runoff vessels.⁸ Other workers also found that 2D TOF suppressed veins better than the 3D techniques.⁹

In evaluating for stenosis, Chien et al.⁹ suggest black-blood techniques to prevent nonvisualization of turbulent spins from

phase incoherence.⁵ Bright-blood methods, on the other hand, may overestimate a stenosis due to phase incoherence.

Mulligan et al. evaluated stenosis from MIP, which simulates the unidimensionality of angiographic studies; however, axial-basis images are more accurate for such assessments.⁵ Also, since they utilize the large FOV, the in-plane resolution of the basis images is worsened. This also compromises the resolution of the MIP.

Cambria et al. reported 98% concurrence between 2D TOF MRA and contrast angiography in 178 patients with a 100% concurrence below the inguinal ligament.¹⁰ Intraoperative confirmation was obtained in the seven bypass grafts performed on the basis of the MRA data alone. Hertz et al. also reported a high correlation between 2D TOF MRA and contrast angiography in assessing arterial stenosis in 19 patients¹¹ (Figure 5). For the popliteal to the dorsalis pedis area, Carpenter et al.⁷ showed MRA to be superior to conventional angiography, with a 48% discordance rate between the two techniques.⁶ This difference appeared to be more progressively pronounced the further distally one examined. Up to 50% of stenosis may be overlooked with conventional angiography if the plaque is en face with no available edge for imaging.

We have found 2D TOF MRA to be accurate in assessing peripheral stenosis. Cross-sectional images are particularly useful, in that they may demonstrate more information than contrast angiography. We showed good agreement in blinded interobserver interpretation (91%).¹¹ Also, lesions distal and proximal to stenosis were seen equally well with MRA, with no appreciable discrepancy between the two.¹¹ We investigated 41 patients for aorto-iliac disease.¹² Only six cases showed a discrepancy between MRA and contrast angiography. Two of these proved to be false-positive on MRA, and two proved to be false-negative. The other two underestimated a greater than 50% stenosis seen on angiography. In the pelvis and lower extremity, we obtained a 62% concordance in a 103-patient series, with no false-positives or false-negatives on MRA.¹³ Contrast angiography failed to show 162 open segments that were confirmed surgically.

We have found MRA to be reliable in assessing vessel patency. Baum et al. demonstrated a 0.7 correlation coefficient between contrast angiography and 2D TOF MRA for determining the parameters of a stenosis.¹⁴ We compared contrast angiography with MRA results in 60 patients with peripheral vascular disease. ROC-curve analysis of one blinded observer demonstrated that location and patency yielded a high correlation between angiography and MRA at our institution.¹⁵

4 PHASE CONTRAST (PC)

Phase contrast techniques utilize motion as an imaging tool, whereby flow is detected in all three axes. A technique relying on phase discrepancy, which measures phase shift of moving spins to determine their velocities, was proposed by Bryant et al.¹⁶ Other investigators demonstrated that cardiac gating imparts accuracy to the calculated arterial flow rates.¹⁷ Various phases of arterial flow could also be better segregated and evaluated. Applications of PC in peripheral vascular disease soon followed. A 2D TOF with PC velocity-sensitive technique demonstrated significantly increased velocities at systole in diseased peripheral vessels after angioplasty, whereas normal

Figure 5 Two-dimensional TOF arteriogram: (a) on a patient who had recently had an angioplasty, demonstrating recurrent stenosis with an intimal flap (arrows); (b) obtained 1 week prior, demonstrating the stenosis (arrow)

vessels demonstrated no alteration in flow.¹⁸ A one spatial- and one-dimensional-variant of PC may enhance tracing of the triphasic flow in the popliteal artery.¹⁹

In our recent experience with two-axis cine-PC angiography for arterial wave patterns in diseased vessels, we have observed monophasicity beyond points of critical stenosis. Simultaneous measurements of velocities at several sites may be implemented with a combined excitation technique to obtain cine-PC data in one dimension, with cardiac gating to generate a second dimension (time).²⁰ Measurements of arterial compliance are made

possible. Addressing arterial compliance is useful in atherosclerotic disease, where compliance is decreased and arterial waveforms are altered. Recently, investigators have demonstrated similar velocity measurements in common iliac arteries with a cine-PC technique with a surgically attached US flow probe on the artery.²¹ Velocity-encoded cine MRA was compared with color-coded US in ten healthy subjects above and below the trifurcation and showed good correlation.²² The classic triphasic pattern was seen. These investigators suggest that velocity-encoded cine MRA may help to evaluate the hemodynamic significance of a stenotic lesion.²³ This information may complement anatomical information obtained from standard 2D TOF MRA. They suggest that a single MRA examination may derive all the information that previously might have been obtained by performing both contrast angiography and duplex US. ECG-triggered 2D PC techniques, where velocity encoding varies with the cardiac cycle, may improve the contrast-to-noise ratio, most notably in small vessels, where up to 260% improved signal has been noted.²⁴ In summary, PC techniques appear to be very promising.

5 3D MRA

While we do not advocate the use of 3D techniques, we will briefly describe their applications. While in 2D imaging, many slices are imaged in sequence, in 3D imaging a volume is imaged. Acquisition of data from a larger volume, as in 3D TOF, enhances spatial resolution and therefore increases S/N. Imaging times are also decreased. Flow compensation is easier with 3D rather than 2D TOF MRA due to the increased gradient amplitude required for slice selection in 2D TOF. In 3D techniques, resolution along the *Y* and *Z* axes is obtained by phase-encoding techniques. Therefore, the slice selection gradient is relatively unburdened. In contradistinction, an extra lobe on the gradient waveform would be necessary to implement flow compensation with 2D techniques, and this would consequently increase the *TE*. Therefore, shorter *TE*s are possible with a 3D modality when utilizing flow compensation in comparison with a 2D modality. So, less dephasing of moving spins occurs with 3D flow compensation. Smaller voxel sizes may also be utilized with 3D imaging. The main disadvantages of 3D imaging techniques, which significantly hinder their usefulness, include decreased sensitivity to slow flows and prolonged reconstruction times of a 3D volume-based data set. In the 3D method, slow flow may incur saturation as it traverses further into the saturation slab. By the same reasoning, venous blood would saturate more readily compared with arterial blood. Therefore 3D MRA may be of greater value in imaging fast flowing and small vessels. Its primary benefits have been seen in the area of neurovascular imaging.

6 ARTIFACTS

Clip artifacts and orthopedic prostheses and artifacts related to susceptibility differences at various interfaces may simulate stenosis or occlusion of a vessel (Figure 6). Local magnetic field variations may be large enough to cause phase dispersion, yielding a net signal intensity vector of zero. Frequently, there is an associated high-signal intensity ring near the metal or air

Figure 6 (a) Frontal projection from a 2D TOF arteriogram through the pelvis demonstrating complete absence of iliac arteries distal to the common iliac artery bilaterally. (b) Coronal scout image demonstrating large artifacts due to the presence of hip prostheses bilaterally

due to misregistration in frequency and slice selection directions as a result of magnetic susceptibility. Gradient echo sequences are particularly vulnerable to these effects.

Due to the length of the examination movement may occur in some patients. Displacement may appear as one translocated, or multiple translocated, slices on the MIP (Figure 7). Motion may create the appearance of a vascular lesion, and individual sections must be reviewed. Peristalsis or respiratory motion may confer high signal intensity on bowel material by 'refreshing stationary spins'. Muscle contraction may confer increased signal intensity to muscle in the same fashion as flowing motion in vessels produces flow-related enhancement.

As discussed previously, pulsatile flow may generate dark, horizontal bands on the MIP, as each section is not obtained at identical times in the cardiac cycle. Thus, varying signal intensities are obtained in each section. This banding artifact, or 'Venetian-blind effect,' is more pronounced in vessels with triphasic flow (Figure 8). Cardiac gating and an increased saturation gap are two ways of counteracting these effects. Phase ghosting, also produced by vessel pulsatility, may be

Figure 7 Lateral MIP projection demonstrating the effect of motion on the MR arteriogram. Displacement of segments of the vessel can simulate stenosis (arrows). Motion can be confirmed by observing motion of the skin line (small arrows)

counteracted with EKG gating. Apparent absence of retrograde arterial flow may occur with the use of a saturation slab which is primarily intended to saturate venous flow. Arterial pulsatility may be confirmed by removing the saturation slab or by acquiring velocity-encoded information.

Turbulence artifacts near a site of stenosis, with its dephasing effects, causes high flow with spin-phase incoherence. However, this is not much of a problem peripherally where flow is less pulsatile. Inspection of axial images for high-grade stenosis would explain the findings.

Potential pitfalls of MIP images occur when a high signal intensity interferes with visualization of a blood vessel, such as from a blood clot. Conversely, a filling defect may become nonapparent if it is surrounded by high signal intensity flowing blood. Also, when section thickness exceeds that of in-plane resolution, normal horizontal flow may appear obstructed on the MIP. In the same vein, pseudobeating may occur with tortuous oblique vessels. This may manifest as a 'stair-step' artifact on the MIP. This may be counteracted by thinner slices, slice overlap, and reacquisition perpendicular to the vessel. Inplane or 'horizontal' flow refers to areas where, due to the orientation or tortuosity of a vessel, flow occurs in a roughly horizontal rather than vertical plane. Since flow in the horizontal plane would not be detected because of saturation, the vascular anatomy would be obscured or underrepresented as stenotic. Examples of this include the anterior tibial artery take-off, which is roughly horizontal or perpendicular to the popliteal artery, and tortuous iliac bifurcations.

1 INTRODUCTION

Recent advances in X-ray, ultrasonic, nuclear, and NMR technologies are making the role of diagnostic radiology increasingly important in the practice of modern medicine. The rapid development of magnetic resonance methods in particular has been most striking. MR has several advantages over X-ray, and MR methods have replaced X-ray methods for many applications. One example of this is the development of MR methods for the visualization of blood vessels within the body. Today this modality is known as magnetic resonance angiography (MRA).

The significance of MRA in medicine cannot be fully appreciated unless one is aware of the competing methods for the generation of blood vessel images. Before the advent of MRA, clinicians generated vascular images using ionizing radiation in the X-ray spectrum. While X-rays of an appropriate energy easily penetrate the body, there is essentially no difference in the X-ray attenuation of blood and surrounding tissue. To overcome this problem, diagnosticians replace blood in a selected vessel with an X-ray-opaque liquid. This contrast media is somewhat toxic and uncomfortable for the patient. In addition, it is typically delivered to the selected blood vessel by a catheter placed into the patient. In light of concerns regarding the ionizing radiation, the toxic effects of the contrast media and a low, but nonzero, mortality rate, the diagnostic benefit of X-ray angiography must be weighed against the risks to the patient.

An alternative to X-rays in vascular radiology is the use of ultrasound. Ultrasonic vascular images are made by observing the reflection of acoustic energy at high frequency. The acoustic attenuation and reflection properties of blood are different from surrounding tissue and frequently provide sufficient contrast to permit the visualization of a vessel. Doppler frequency shifts in the ultrasonic signal can also be used to highlight moving blood. While ultrasonic measurements carry none of the risks of X-ray methods, they are limited in their applications to only a few clinical applications. For example, vessels that are obscured by bone cannot be observed. Vessels deep within the body, or hidden by a thick layer of adipose tissue, are also difficult or impossible to detect. Another aspect of ultrasonic detection is that the resulting images are heavily dependent on the skills of the operator, since the ultrasonic probe must be manipulated at the surface of the patient.

Magnetic resonance angiography overcomes many of the problems of X-ray angiography and ultrasonic imaging. The

MRA techniques employed today fall into two classes of technique that are defined by the two different ways in which macroscopic motion of nuclear spins influences the creation and detection of an NMR signal.

The first class of methods relies on the macroscopic displacement of longitudinal magnetization. The phenomenon was first observed and used by Singer and others long before the advent of MR imaging.¹⁻³ Today, MRA methods of this type are frequently referred to as 'time-of-flight' methods (see *Time-of-Flight Method of MRA*).

The second class of MRA methods relies on a very different phenomenon. These methods exploit the change in the phase of transverse spin magnetization which occurs when nuclear spins move along a magnetic field gradient. The phenomenon was first reported by Hahn⁴ in 1960, and was recognized as a major source of artifacts in the early development of MRI.^{5,6} The utility of motion-induced phase shifts for the detection of flow was also recognized^{7,8} and many phase-sensitive MRA methods have since been proposed and demonstrated. This article will attempt to describe the more widely used methods of phase-sensitive MRA and provide an overview of the unique aspects of this class of imaging methods.

2 PRINCIPLES OF PHASE DETECTION OF MOTION

2.1 Bipolar Gradient Pulses

The fundamental phenomenon which is the source of many motion-induced artifacts in MRI and the source of motion-based contrast in MR angiograms is the effect that a magnetic field gradient pulse has on transverse spin magnetization. This effect is illustrated in Figure 1. In Figure 1, longitudinal spin magnetization is first generated by an excitation rf pulse. A flow-encoding magnetic field gradient pulse is then applied. This flow-encoding pulse induces a phase shift which is proportional to velocity. Phase-sensitive MRA methods use this phase shift to discriminate between moving nuclear spins and those that are stationary.

Figure 1 Velocity-induced phase shifts. All phase-sensitive velocity imaging and measurement with magnetic resonance follows these steps. First, transverse spin magnetization within the sample is generated by applying a radiofrequency pulse at the Larmor frequency. A flow-encoding gradient pulse is then applied. This flow-encoding gradient pulse induces a phase shift which is directly proportional to velocity

Figure 2 The bipolar flow-encoding gradient pulse. The first lobe dephases transverse magnetization by an amount proportional to position. The second lobe rephases the magnetization. If the magnetization moves in the interval between the pulses, however, the cancellation of the induced phase shift is incomplete. The residual phase shift is proportional to velocity

The simplest flow-encoding magnetic field gradient pulse is shown in Figure 2. This pulse consists of two lobes, separated by a time interval, T . These gradient lobes are applied in the same direction, but with opposite polarity. The unsigned area of each lobe, A_g , is identical. The phase shift induced by velocity, Φ , can be expressed as:

$$\Phi = \gamma V T A_g \quad (1)$$

where γ is the gyromagnetic ratio of the nuclear spin, and V is the velocity of motion.

The effect of a flow-encoding gradient on transverse spin magnetization is illustrated in Figure 3. In Figure 3, two bodies

Figure 3 The effect of a bipolar gradient pulse on the phase of stationary and moving spin magnetization. The first magnetic field gradient lobe of the bipolar pulse induces a phase shift that is proportional to position. The second lobe also induces a phase shift, but this phase shift has the opposite sign. The phase shifts induced in stationary nuclei by the first and second lobes, Φ_{S1} and Φ_{S2} , cancel upon subtraction. The phase shifts for moving nuclei, Φ_{M1} and Φ_{M2} , on the other hand, are not equal and thus do not entirely cancel. The residual phase shift is proportional to the nuclei's velocity

of nuclear spins are shown. The first body is located some distance from the center of the magnetic field gradient and remains stationary during the flow-encoding gradient pulse. The second body of nuclear spins is also located along the magnetic field gradient, but is moved during the time interval between the gradient lobes.

Before application of the first lobe of the flow-encoding gradient, transverse spin magnetization is generated and exists with a phase shift, which for the sake of simplicity is assumed to be zero. The application of the first gradient lobe causes the strength of the magnetic field to be proportional to position for the duration of the lobe. Since the Larmor frequency of the transverse spin magnetization is directly proportional to the strength of the magnetic field, during the application of the lobe, nuclear spins will have a resonant frequency that is proportional to location. After the lobe is finished, the magnetic field is homogeneous once again (i.e. all transverse spin magnetization resonates at the same frequency), but the transverse spin magnetization will have acquired a phase shift. This phase shift is proportional to the strength and duration of the lobe, and is also proportional to the location of the nuclear spin along the applied magnetic field gradient.

The phase shift induced by the first lobe in Figure 3 can be undone by the application of a second lobe having equal amplitude and duration, but having opposite polarity. If the nuclear spins do not move during the interval between the gradient lobes, the phase shifts induced by the first lobe will be canceled by the second lobe. If, on the other hand, the nuclear spins move during the interval between gradient lobes, the phase shift induced by the first lobe will not be exactly canceled by the phase shift induced by the second lobe. The residual phase shift will be proportional to the distance the nuclear spins have moved and hence will be proportional to the velocity of the nuclear spins.

2.2 Higher Order Gradient Pulse Waveforms

A bipolar magnetic field gradient pulse is only one member of a series of magnetic field gradient pulse waveforms which induce phase shifts in transverse spin magnetization. Single-lobed gradient pulses induce phase shifts that are proportional to position and are used to encode position in conventional MRI. Bipolar gradient pulses are simply two spatial-encoding gradient pulses applied at slightly different times so that changes in position during the bipolar pulse give phase shifts that are proportional to velocity. Higher orders of motion such as acceleration and jerk can be detected with more complicated gradient waveforms, which can be constructed with linear combinations of simpler gradient waveforms. An illustration of this concept is shown in Figure 4.

2.3 Detecting Velocity with Phase

Once transverse spin magnetization has been given a phase shift that is proportional to velocity, several strategies can be employed to selectively detect signals arising from moving nuclear spins in the presence of signals from stationary spins. Since flow-encoding gradient pulses are only one of many potential sources of phase shifts in transverse spin magnetization, the direct detection of phase itself is usually impractical. Fortunately, phase shifts induced by phenomena other than flow can

Figure 4 Construction of an acceleration (Acc)-encoding magnetic field gradient pulse waveform by combining two velocity-encoding waveforms. Note that the two different waveforms induce different phase shifts

easily be removed through a variety of modulation schemes. For example, an early method described by Wedeen et al.⁹ relied on the modulation of velocity that occurs in arteries. With this method, two complex images were obtained. Each image was acquired with a flow-encoding gradient. The first image was acquired during the period of peak velocity in the cardiac cycle (systole) and the second was acquired during a period of low flow (diastole). During periods of high velocity, large phase shifts were induced in the MR signals. These phase shifts were frequently so large that distributions of velocity within an image voxel would cause attenuation of the MR signal by phase cancellation. Since the only aspect of the detected MR signal that was different in each acquisition was the phase cancellation arising from velocity, only signals from moving blood were retained upon subtraction of the two images.

A major disadvantage of the cardiac gated scheme described above was that only pulsatile blood flow could be visualized. One strategy that was designed to overcome this limitation employed an amplitude modulation of the flow-encoding gradient waveform.^{10,11} As with Wedeen's technique, moving blood was distinguished from stationary tissue by phase cancellation arising from a distribution of velocities as shown in Figure 5.

An alternative modulation scheme that has found widespread use^{12–16} is outlined in Figure 6. With this method, two sets of data are acquired under identical conditions, except for the polarity of the flow-encoding gradient pulses. The amplitude of each flow-encoding gradient is kept small to minimize phase cancellation caused by velocity distributions within a pixel, and yet is large enough to cause a detectable phase shift in the MR signal.

Velocity information contained within MR signals detected with modulated flow-encoding gradient pulses can be extracted in several ways.¹⁷ The simplest method is to subtract the magnitude of each image data set. This is only useful, however, if the data are amplitude-modulated (i.e. the modulation scheme causes phase cancellation of MR signals for one of the acquired data sets). More commonly, the extraction of velocity information is performed by complex arithmetic on the image data.

Figure 5 Use of phase cancellation to modulate the amplitude of the MR signal. With this strategy data are acquired under two conditions. The first data set is acquired under conditions which cause loss of signal due to phase cancellation caused by motion. The second data set is acquired under identical conditions to the first, except that the phase cancellation is not performed. The two acquired data sets are identical except for that part arising from motion

Two methods for the extraction of velocity information are currently in use. The first method is the computation of the magnitude of the complex difference. A vector representation of the generation of complex difference data is shown in Figure 7. Images acquired in this way have an angiographic appearance in which stationary features have little or no signal intensity, and moving blood appears bright. Complex difference data are relatively insensitive to the presence of stationary spin magnetization within the voxel, but provide pixel intensities that are not linearly related to velocity as shown in Figure 8. The relationship between pixel intensity, I , and velocity is:

$$I = K \text{abs}[\sin(\gamma V T A_g)] \quad (2)$$

where K is a constant of proportionality. The problem of nonlinearity is frequently minimized by choosing flow-encoding gra-

Figure 6 Phase modulation of the MR signal. With this strategy data are acquired under two conditions. The first data set is acquired with a flow-encoding gradient pulse which induces a discrete phase shift due to motion. The second data set is acquired under identical conditions to the first, except that the polarity of the flow-encoding gradient pulse is reversed. The two acquired data sets are identical except for that part arising from motion

Figure 7 Vector representation of complex subtraction in phase contrast angiography. Two data sets are collected. The first is collected with a bipolar gradient pulse (e.g. a positive lobe followed by a negative lobe) which induces a phase shift that is proportional to velocity. The second is collected in an identical fashion except that the polarity of the bipolar gradient is reversed (e.g. a negative lobe followed by a positive lobe). The complex difference of these two data sets is then calculated. Note that the complex difference of stationary tissue is zero, but that of moving blood is represented by a nonzero length vector

dient pulses that are only strong enough to cause a 1 rad phase shift for the highest expected velocity. Under this condition, the assumption:

$$x \approx \sin(x) \quad (3)$$

holds and the pixel intensity becomes approximately proportional to velocity.

The second method for the extraction of velocity information from complex data is outlined in Figure 9. With this method, the phase of data in each data set is computed. The difference between the phase of the first and second data set is then computed to give a phase difference data set. The intensity of each pixel in the final image is set equal to the phase difference. The pixel intensity of phase difference data is linearly proportional to velocity, but its dependence on velocity is discontinuous and has a periodicity of π as shown in Figure

Figure 8 The relationship between velocity and image pixel intensity when complex differences are employed. The magnitude of the complex difference does not include directional information and is only approximately linear with respect to velocity as long as the velocity-induced phase shift is small. If the phase shift is too large, it becomes indistinguishable from a smaller phase shift (an effect called aliasing)

Figure 9 Vector representation of phase difference computations in phase contrast angiography. Two data sets are collected. The first is collected with a bipolar gradient pulse (e.g. a positive lobe followed by a negative lobe) which induces a phase shift that is proportional to velocity. The second is collected in an identical fashion except that the polarity of the bipolar gradient is reversed (e.g. a negative lobe followed by a positive lobe). The difference of the phases of these two data sets is then calculated. Note that if the data contain contributions from both stationary tissue and flowing blood (as shown), then the phase shift of the stationary tissue must be removed before the phase difference due to flow can be calculated

10. Note that when phase differences are computed it is important to remove static phase shifts arising from resonance offset conditions in order to maintain the expected relationship between velocity and phase.

When pixel intensity is set equal to the phase difference of the acquired data, the images have a unique appearance. Stationary tissue and regions devoid of signal typically appear gray in color. Blood flowing in the direction of the flow-encoding gradient pulse, however, has bright signal intensity which is proportional to velocity. Blood flowing in the opposite direction appears dark.

Figure 10 Relationship between velocity and image pixel intensity when phase differences are employed. Note that phase shifts are directly proportional to velocity. If the phase shift is too large, however, it becomes indistinguishable from a smaller phase shift. Note that phase difference displays produce a more linear response than magnitude displays, but have more severe discontinuities in the event of velocity aliasing

A phase difference display is frequently used when a quantitative velocity image is desired. To ensure the quantitative nature of the image, however, phase offsets arising from sources other than velocity must be removed. These sources include resonance offset conditions such as transmitter offsets, field inhomogeneities, chemical shift phenomena, and eddy current effects.

2.4 Strategies for Vessel Selectivity

In clinical practice it is frequently useful to limit the number and nature of the blood vessels imaged in an angiogram. In X-ray angiography this is accomplished by injecting the contrast media into the selected vessel using a catheter. Since MRA uses the motion of blood for contrast, a selective injection is not possible. Fortunately, several strategies exist to permit the selective detection of blood vessels.

Perhaps the most frequently used strategy for selectively detecting vessels is the use of saturation zones around the region of interest. Saturation zones are regions that are subjected to strong rf pulses, typically having a flip angle of between 90 and 135°. These pulses are applied repeatedly, and cause the longitudinal magnetization of tissue within the zone to become saturated. Blood traveling through the zone also becomes saturated. Blood leaving the saturation zone and entering the region of interest is made invisible since transverse spin magnetization cannot be created when longitudinal magnetization has been destroyed. Once the blood has been in the region of interest for a while, however, its longitudinal magnetization reaches a new steady state, and the blood may become visible. Saturation zones are useful in many clinical applications, particularly those in which the targeted vessel crosses from the saturation zone to the region of interest only once.

A second mechanism that can be employed to selectively detect vessels with phase-sensitive MRA relies on differences in blood velocity. This is possible because the size of the flow-encoding gradient pulses can be tailored to cause maximum phase shifts for a selected range of velocities. Smaller flow-encoding gradient pulses will induce phase shifts in only the highest velocities, and have little effect on slowly moving blood. Since arteries typically carry relatively high velocity blood and veins have lower velocity blood, phase-sensitive angiograms using small flow-encoding gradient pulses usually highlight arterial structures. Venous structures can be highlighted by increasing the strength of the flow-encoding gradient pulses. Increasing the strength of the flow-encoding pulses will cause the phase shifts arising from higher velocities to exceed π and the pixel intensity of arterial structures will no longer be proportional to velocity.

In the body, arterial blood tends to be pulsatile while venous blood flows more smoothly. The nature of arterial pulsatility depends on the location of the artery within the body and is heavily influenced by the presence of stenosis. This is illustrated in Figure 11. Data acquisition strategies that highlight pulsatile flow and suppress steady flow can be devised if data are acquired synchronously with the cardiac cycle. For example, pulsatile flow can be highlighted in an angiogram by acquiring images at multiple points in the cardiac cycle and computing the standard deviation of each pixel.

Figure 11 Blood velocity during the cardiac cycle in several locations within the body. Note that the velocity profile is dramatically different in different vessels and is influenced by vessel disease

2.5 Multiplexed Detection of Multiple Flow Components

The flow-encoding gradient pulses used in phase-sensitive MRA induce phase shifts that are proportional only to the component of velocity that is parallel to the direction of the applied magnetic field gradient. Consequently, to construct an angiogram that contains information for all components of velocity, data from three orthogonal flow-sensitive directions must be acquired. Since each flow-sensitive direction requires that data be collected twice, a total of six acquisitions are required.

The information present in a six-excitation phase contrast angiogram has only four components (i.e. stationary tissue and velocity in three orthogonal directions). It is possible to acquire this information more efficiently using a four-excitation multiplexing scheme. One such scheme¹⁸⁻²⁰ is based on the Hadamard transform. With this method four excitations are performed, each having flow-encoding gradient pulses applied in all three orthogonal directions simultaneously. The combination of flow-encoding pulse polarities is unique in each excitation. One possible combination of flow-encoding pulse polarities is:

Excitation	Gradient axis		
	X	Y	Z
1	+	+	+
2	-	-	+
3	-	+	-
4	+	-	-

where + and – denote the polarity of the applied flow-encoding gradient pulse. The four components of information can be extracted by computing appropriate linear combinations of the acquired data. For the modulation scheme shown above, the linear combinations take the form:

$$\text{Stationary tissue} = Ex_1 + Ex_2 + Ex_3 + Ex_4 \quad (4)$$

$$X \text{ flow component} = -Ex_1 + Ex_2 + Ex_3 - Ex_4 \quad (5)$$

$$Y \text{ flow component} = -Ex_1 + Ex_2 - Ex_3 + Ex_4 \quad (6)$$

$$Z \text{ flow component} = -Ex_1 - Ex_2 + Ex_3 + Ex_4 \quad (7)$$

where Ex_i represents data from the i th excitation.

3 IMPORTANT ATTRIBUTES OF PHASE CONTRAST MRA

There are several important attributes that distinguish phase-sensitive MRA from time-of-flight MRA and from X-ray angiography. For example, each datum collected in a phase-sensitive procedure is sensitive only to a single component of flow. Thus, if a complete angiographic image is required, data must be collected at least four times to obtain all three velocity components and the stationary tissue component. This is in contrast to the single detection required for most time-of-flight procedures. A phase-sensitive angiogram does not necessarily take four times longer to collect than a time-of-flight angiogram, however, since the optimum repetition time, TR , for a phase-sensitive angiogram is the minimum available on the system (e.g. 16 ms) whereas the optimum repetition time for a time-of-flight angiogram is longer (e.g. 40–50 ms) to permit the inflow of nonsaturated spin magnetization.

A second attribute of phase-sensitive angiography is that image acquisition is relatively independent of the field-of-view. This is because the source of image contrast in a phase-sensitive angiogram is motion. With phase-sensitive MRA, images of slowly moving blood in small vessels can be acquired within small fields-of-view as easily as higher velocity blood travelling in larger vessels within a large field-of-view. Time-of-flight angiography, however, is constrained by the requirements of vessel geometry and blood velocity to ensure that the inflow of relaxed blood into the region of interest is optimized.

Because the only source of image contrast in a phase-sensitive MR angiogram is motion, excellent suppression of background signals from stationary tissue is possible. Full suppression of background tissue with time-of-flight methods, however, is difficult since the source of image contrast in time-of-flight methods is differential levels of spin saturation. Consequently, the saturation of spin magnetization to suppress stationary tissue signal in time-of-flight angiography also suppresses signals from moving blood. Another consequence of the time-of-flight contrast mechanism is that tissue having short T_1 [e.g. mucus and neoplasms after an injection of Gd-diethylenetriaminepentaacetic acid (Gd-DTPA)] can appear with the same pixel intensity as moving blood. Different levels of spin

saturation among tissues can also occur in phase-sensitive angiography, but this does not affect the suppression of stationary tissue, and partially saturated blood appears with only a reduced signal intensity.

One attribute of phase-sensitive methods that has found extensive use is their quantitative nature. Several nonangiographic methods are currently in use. These include thin-slice methods in which vessels are imaged in cross section and the intensity of each pixel of the image is made proportional to the flow-induced phase shift.^{21–23} An alternative approach is the conversion of one image dimension into a velocity dimension.^{24–27} Images acquired in this fashion are not affected by artifacts arising from background phase shifts and are similar in appearance to Doppler ultrasonic images.

Another characteristic of phase-sensitive MR angiographic methods is that they are heavily dependent on the quality of the instrument. This is particularly true with respect to phase stability since phase shifts are used to detect and measure motion. Perhaps the most common source of phase instability in an MRI system is eddy currents. These eddy currents are induced in metallic structures within the magnet by magnetic field gradient pulses. Phase instability can also occur in the transmitter and receiver subsystems of the instrument. Fortunately, most modern MRI systems are stable enough to perform phase-sensitive angiography.

4 PHASE-SENSITIVE FLOW IMAGING PULSE SEQUENCES

4.1 Two-Dimensional Phase Contrast MRA

The earliest implementations of phase-sensitive MRA^{9,12} were similar to X-ray methods in that they provided two-dimensional (2D) projections of the region of interest. In these methods the thickness of the imaged volume was often made to be the full thickness of the patient. If slice selection was employed at all, it was often used to excite a thick slab of magnetization orthogonal to the image plane. Today 2D phase contrast MRA is rarely performed as a full projection. Instead, one or more thick slices are typically obtained from the region of interest.

The speed of 2D phase contrast procedures can be advantageously used in a number of ways. For example, speed can be used to shorten the overall patient examination time. Quite often, however, it is useful to acquire additional data to provide more diagnostic information. With 2D phase contrast MRA, this might include additional view angles or slice locations. Alternatively, certain types of artifacts can be minimized by acquiring additional data. For example, phase-encoding artifacts arising from changes in blood velocity during the cardiac cycle can be minimized by detecting the average velocity-induced phase shift rather than one detected at an arbitrary instant in time. This can be done by acquiring data with a relatively large NEX. For example, with a repetition time, TR , of 50 ms and a heart rate of 60 beats per minute, choosing NEX to be about 20 will cause velocity variations during the cardiac cycle to be averaged.

4.2 Cine Phase Contrast MRA

An early variant of 2D phase contrast MRA was the use of cardiac gating and the detection of images at multiple points in the cardiac cycle.^{14,15} Cine MRA is particularly useful in imaging peripheral arteries since blood flow in these vessels is typically triphasic and moves forward, backward, and remains still at different points of each cardiac cycle. Arterial flow dynamics can be exploited to differentiate arterial flow from venous flow.

Thin-slice cine phase contrast imaging in which the phase of each pixel is displayed^{21–23} has become widely used in the past few years. These images provide a quantitative measure of blood velocities during the cardiac cycle and have been applied in the head,²⁸ aorta,²⁹ renal,³⁰ mesenteric,³¹ and peripheral vessels.³²

4.3 Three-Dimensional (3D) Phase Contrast MRA

Two-dimensional phase contrast angiograms have several limitations that can be overcome by the collection of the data in three dimensions.¹⁶ Unlike a projection angiogram, a typical 3D angiogram has approximately isotropic voxels. Phase variations across a voxel are minimized because the voxel dimensions are small. Perhaps the most significant advantage, however, is that the data can be analyzed retrospectively in a number of ways. For example, 2D projections can be generated for any view angle. Selected subsets of the acquired data can be extracted to remove features that interfere with the presentation of features of interest. With 3D MRA it is also easy to generate cross-sections of vessels.

4.4 Fourier Velocity Encoding

Fourier velocity-encoding pulse sequences are a form of phase-sensitive velocity imaging in which the velocity of spin magnetization is represented as a positional displacement rather than as a phase shift in the image. These pulse sequences are equivalent to conventional spin warp imaging pulse sequences, except that the spatially localizing phase-encoding gradient pulses are replaced with bipolar flow-encoding gradient waveforms. In other words, a Fourier velocity-encoded image has a phase-encoded dimension in which displacement of signal depends on spin velocity rather than on spin position. Pixel intensity in these images is determined by the sensitivity of the imaging system and the strength of the detected MR signal. The phase of each pixel, however, is determined by resonance offset conditions such as transmitter offsets, field inhomogeneities, and susceptibility effects. As with conventional MR imaging, this phase information is typically ignored.

Figure 12 shows an example of Fourier velocity-encoding applied in the human abdomen. In this image the horizontal dimension is a spatial dimension corresponding to the subject's left/right axis. The vertical axis, however, is a velocity dimension corresponding to the component of velocity parallel with the subject's inferior/superior axis. Excitation of spin magnetization was limited in this image to a 5 mm axial slice. Note that the distribution of velocities within the aorta is narrow, but the distribution of velocities within the vena cava is relatively broad.

Figure 12 Fourier velocity-encoded image of the abdomen. In this image one spatial dimension and one velocity dimension have been collected. Images of this form can be used to measure the distributions of velocity within a vessel. Since they use a phase-encoding mechanism to detect velocity, these images have a velocity precision and accuracy equivalent to that of spatial measurements in conventional imaging. (Reproduced by permission from C. L. Dumoulin et al.²⁷)

5 POSTPROCESSING

Many of the MRA methods in current use acquire data in three dimensions. For example, a 3D phase contrast angiogram has three spatial dimensions. Cine 2D phase contrast angiograms are also 3D, but consist of two spatial dimensions and a temporal dimension. Unfortunately, 3D data cannot be displayed directly with the hardware available in most institutions. Rather, a 2D subset of the 3D data set must be extracted and put into a suitable form such as film for diagnosis. Several methods currently in use are outlined below.

5.1 Maximum Intensity Projection

Filming thin-slice extractions of a 3D data set is straightforward and often useful. Projection images in which one of the three dimensions is collapsed, however, are usually more helpful. The simplest and most commonly used projection algorithm is the Maximum Intensity Projection (MIP) method. With MIP a 'ray' is sent through the 3D data set to create each pixel in the projection. The maximum pixel intensity value found along the ray determines the pixel value in the projection image as shown in Figure 13. An important aspect of MIP is that vessels close to the viewer are indistinguishable from vessels further away. Depth information can be recovered, however, by sequentially displaying several MIP projections at a variety of view angles to create the illusion of a 3D object.

5.2 Subvolume Reconstruction

In an ideal MR angiogram the pixel intensities of blood vessels and stationary tissue are different enough to guarantee

Figure 13 Projection of the maximum intensity pixel to extract a 2D image from a 3D data set. In this procedure ‘rays’ are sent through the 3D object. A 2D projection is created by reducing the data encountered by each ‘ray’ to a single value. With the *maximum intensity projection* (MIP) algorithm, the value of the most intense pixel is chosen for the projection image. Here two ‘rays’ are shown. The first ‘ray’ (a) encounters the bright signal in a vessel and selects the most intense pixel. The second ‘ray’ (b) also selects the brightest pixel, but this pixel contains noise

that only vessels are detected with an MIP algorithm. Complete suppression of stationary tissue, particularly for time-of-flight procedures, is often impossible, however, and the MIP algorithm projects the most intense pixels of the stationary tissue background. This makes small vascular features having relatively low pixel intensity more difficult to detect. Fortunately, the appearance of nonsuppressed tissue can be minimized by applying the MIP algorithm only over a selected subvolume of data. In addition to improving vessel contrast in the projection image, subvolume reconstructions can be used to remove overlapping blood vessels to enhance the appearance of the vessels of interest.

5.3 Temporal Filtering

Data that are acquired with a temporal dimension can also be subjected to projection procedures. The appearance of all vessels within a dynamic image can be enhanced by applying the MIP algorithm in the temporal dimension. Alternatively, the standard deviation of pixel intensity, rather than the maximum pixel intensity, along the ray can be determined to highlight dynamic features, such as arteries. Features that are more constant during the cardiac cycle, such as veins and background, are suppressed. Arterial blood flow downstream from

an occlusion or high-grade stenosis, however, may no longer be pulsatile and a standard deviation projection may suppress rather than enhance the appearance of the vessel.

6 APPLICATIONS

Phase contrast MRA is frequently used in clinical evaluations to display pathologic flow conditions. The principle reasons for using phase contrast methods are: (1) to improve vessel detection by subtracting the background signal and (2) to utilize the velocity/phase relationship to provide physiological information regarding blood flow. The flexibility of phase contrast methods makes them somewhat more complex to use than time-of-flight methods in the clinical environment. Nevertheless, phase contrast methods are becoming increasingly valuable for the evaluation of patients with suspected vascular disease.

6.1 The Role of Flow-Encoding Strength in Phase Contrast MRA

The amplitude of the bipolar flow-encoding gradient pulse determines the amount of velocity encoding. A larger amplitude will sensitize the MR angiogram to low velocities. Conversely, a small amplitude will produce an angiogram that emphasizes higher velocities.³³ One can therefore create phase contrast angiograms that display pathologic conditions by selecting a velocity encoding that closely approximates the pathologic flow state. Encoding for slower flow velocities can improve detection of slow flow within venous structures such as the dural sinuses or deep cerebral veins. Encoding for slow flow can also improve visualization of small arterial structures as illustrated in Figure 14. In general, when one wants to optimize visualization of intracranial arterial structures a velocity encoding of 30 cm s^{-1} is preferable to improve detection of the slow blood flow along the vessel wall and to help define small vessels and pathologic vessels with reduced flow velocities. Similarly when phase contrast techniques are used to identify aneurysms, it is important to use a low-velocity encoding in order to optimize visualization of slow vortex flow in the central portions of the aneurysm.³⁵ Phase wrap (or flow aliasing) is not a serious problem in phase contrast ‘speed’ imaging (i.e. when the magnitude of the data is displayed), because the higher velocity spins typically occur in the center of the vessel and the vessel morphology will still be well delineated by visualization of the slower flow along the edges of the vessel.

By selecting a higher velocity encoding ($100\text{--}150 \text{ cm s}^{-1}$) and using phase-difference reconstruction, images can be obtained that preserve the quantitative phase/velocity relationships and emphasize higher velocity flow structures. This can be advantageous for identifying high-flow arteries that supply arteriovenous malformations or higher velocity inflow jets associated with intracranial aneurysms. Phase-difference images also permit the sign of the flow-induced phase shift to be encoded as pixel intensity. This is particularly useful for determining the direction of flow within vessels.

Figure 14 Coronal 2D phase contrast angiogram of the vertebral arteries at two velocity encodings. (a) This image was obtained with a velocity encoding of 40 cm s^{-1} . The right vertebral artery is not visualized and was initially thought to be occluded. (b) The angiogram was repeated with a velocity encoding of 10 cm s^{-1} . The slow flow in the small, right vertebral artery is now visualized (large arrows). The slow flow along the wall of the left vertebral artery is also demonstrated (small arrows). Note that the central higher velocity flow has aliased and appears as reduced signal intensity (open arrow). (Reproduced by permission of Raven Press from C. A. Anderson et al.³⁴)

6.2 MRA and T_1 Relaxation Agents

Blood flowing into the region of interest reaches a steady state having reduced signal intensity after experiencing multiple rf pulses. This saturation of slowly moving blood is particularly problematic for time-of-flight MRA since the intensity of blood is ultimately reduced to that of the surrounding background tissue. Saturation of slowly moving blood can also be a problem with phase contrast MRA, but since the background signal intensity in a phase contrast angiogram is zero, saturation merely reduces the signal-to-noise ratio of the blood signal and the vessel is usually still visible. Nevertheless, slowly moving blood would be easier to detect if the equilibrium magnetization could be increased. This can be accomplished by shortening the T_1 of blood by administering a relaxation agent such as Gd-DTPA.

With a T_1 relaxation agent in the bloodstream, flowing blood reaches a steady state, which gives a stronger MR signal. Higher concentrations of the relaxation agent result in a shorter T_1 and a corresponding increase in the steady state magnetization. For Gd-DTPA this relationship holds for concentrations up to 0.5 mM kg^{-1} . At higher doses the T_2 shortening effects become dominant and the MR signal intensity begins to decrease.^{35,36}

The effects of intravenous contrast enhancement for phase contrast methods is related to velocity encoding. At higher velocity encodings slow flow has relatively low signal intensity and is poorly visualized. In this instance, intravenous contrast material will significantly improve the detection of slow flow. This is particularly advantageous in four clinical situations.

6.2.1 Small Arteries

Frequently small arteries with minimal flow are difficult to detect. This is due to saturation of slowly moving blood as it passes through the imaging volume. An incorrect diagnosis of vascular occlusion might be made when in fact the vessel is patent. By administering intravenous contrast material the signal intensity associated with the slowly moving blood increases by a factor of two, making the vessel easier to detect. This increase in signal results in an increase of the dynamic range of detectable velocities. An example of increased sensitivity to slow flow after injection of a T_1 relaxation agent is shown in Figure 15.

6.2.2 Venous Structures

Imaging venous structures is improved by the use of intravenous contrast material by decreasing the saturation of slow venous flow especially along the wall of the vein. This is particularly important in cases of dural sinus thrombosis where collateral flow may be difficult to detect due to its very slow flow rates.

6.2.3 Complicated Flow

Vortex flow within aneurysms may also result in signal loss due to saturation effects. By shortening the T_1 of blood, the lumen of the aneurysm may be better defined.

6.2.4 Increased Spatial Resolution

Increasing spatial resolution results in reduced signal-to-noise for most MRA acquisitions. Intravenous contrast enhancement enables more highly resolved matrices and smaller fields-of-view to be used by increasing the signal associated with small vessels.

Figure 15 Gd-DTPA-enhanced phase contrast MRA. (a) The nonenhanced axial phase contrast angiogram was obtained using a 256×256 matrix and a field-of-view of 20 cm. (b) After the administration of Gd-DTPA at a dose of 0.1 mM kg^{-1} , the scan was repeated using identical imaging parameters. Smaller arterial branches (arrows) as well as venous structures (open arrow) can now be identified

6.3 Clinical Applications in the Head and Neck

Phase contrast angiography has proven useful in the head,^{37,38} neck,³⁹ abdomen,^{40,41} and peripheral vessels.^{42,43} Rather than provide a complete atlas of examples, only applications in the head will be discussed below.

6.3.1 Cerebral Ischemia

The ability to quantify flow velocity and flow volumes with phase contrast MRA has added a new dimension to the MRA evaluation of neurological disease. In addition to demonstrating vascular morphology, phase contrast MRA can now determine the adequacy and character of blood flow for specific vessels. The goals of the MRA examination are to identify compromised blood flow and to determine the severity and etiology of the flow reduction. Usually, reduced or absent flow within the internal carotid, vertebral, basilar, anterior, middle, and posterior cerebral arteries can be identified with a high degree of accuracy.

There are four pathologic flow conditions that are generally recognized as leading to cerebral ischemia or infarction. The first is global hypoperfusion due to sustained hypotension. The second is thrombosis of the small perforating arteries leading to infarction of deep structures such as the basal ganglia or white matter. The third category is embolic disease in which atherosclerotic material or thrombus dislodges from a preexisting atheromatous lesion, producing flow compromise distally in smaller branch vessels. The last condition is the complete thrombosis of a major vessel resulting in decreased or absent distal perfusion.^{44,45} MRA can frequently determine which of these mechanisms is responsible for the patient's ischemic event in a fashion analogous to X-ray angiography.⁴⁶⁻⁴⁸

Patients may present with anterior circulation, large artery ischemic events (i.e. motor or sensory deficits) requiring attention to the carotid bifurcations (Figure 16), the proximal middle cerebral arteries, and possibly the aortic arch. Other patients may present with ischemic events related to the larger posterior circulation vessels (i.e. ataxia, dizziness, nausea, cranial nerve dysfunction). In this instance, the proximal and distal vertebral arteries and basilar artery must be evaluated (Figure 17). For patients presenting with embolic events, the embolic material may arise from the heart or the proximal arterial system. If the transient ischemic attacks occur in multiple vascular territories, a cardiac source for emboli should be sought. If previous transient ischemic attacks have occurred in the same vascular territory, a localized proximal vascular lesion is the most likely etiology.⁴⁹

Intracranial MRA examination can be approached in several ways. The most commonly used method is a 3D time-of-flight acquisition which includes the circle of Willis, the proximal middle cerebral arteries, and the distal basilar artery. This approach is effective for evaluating the proximal vessels. Unfortunately, time-of-flight angiography is not particularly sensitive to slow flow, and there may be instances in which vessel patency is overlooked due to saturation of the slow flow distal to an area of severe stenosis. An alternative approach is to obtain a 2D or a 3D phase contrast angiogram with low velocity encoding (e.g. 20 cm s^{-1}).⁵⁰ These images can define the vascular morphology in the region of reduced flow. In addition, cine phase contrast studies can be performed to display flow direction⁵⁰ and to permit quantitative measurements of flow

(a)

(b)

(c)

Figure 16 Right internal carotid artery stenosis demonstrated by 2D phase contrast MRA. (a) The coronal 2D phase contrast image demonstrates a stenosis of the proximal right internal carotid artery. Flow is symmetric in both internal carotid arteries. Sagittal 2D phase contrast MRA images clearly define (b) the normal left internal carotid artery, and (c) the stenotic proximal right carotid artery (arrow)

and velocity. In selective instances, this can be helpful for defining the hemodynamic effects of vascular lesions.

MRA evaluation of the extracranial carotid arteries is currently a source of controversy.^{51,52} Most investigators rely on single slab or multiple slab 3D time-of-flight MRA to define

Figure 17 Basilar artery occlusion demonstrated by phase contrast MRA. (a) The axial and (b) the coronal phase contrast angiograms indicate absence of flow within the basilar artery and only minimal flow in the right and left vertebral arteries (arrows)

the degree of vessel compromise.⁵³ Some authors have recommended performing a 2D time-of-flight study whenever a carotid occlusion is encountered to avoid missing a nearly occluded internal carotid artery.^{54,55} Unfortunately, high velocities caused by a severe stenosis may cause a signal loss in 2D time-of-flight angiography. Carefully controlled trials will ultimately be needed to define precisely the accuracy of MRA for defining carotid stenosis. There is no question, however, that MRA is capable of providing high-resolution images that are adequate for many clinical management decisions.

6.3.2 Vascular Malformations

Arteriovenous malformations (AVMs) are most commonly supratentorial where a large component of the AVM is located superficially in the pia. The malformation occasionally has a wedge shape with the apex of the wedge directed toward the ventricular system. The amount of parenchymal component of the AVM is variable. Occasionally vascular malformations may have both dural and pial components and are thus termed mixed AVMs. Malformations completely restricted to the dura are termed dural AVMs. Spinal vascular malformations are most often dural in location and frequently contain direct arteriovenous fistulas.⁵⁶

The nidus of the AVM may be variable and difficult to characterize accurately. The nidus has been defined as 'that part of the malformation interposed between the recognizable feeding arteries and the larger terminal draining veins'. The nidus represents the area of arteriovenous shunting within the malformation. It is therefore the low-resistance portion of the malformation and is thus responsible for the hemodynamic changes related to the malformation. The venous drainage begins as the multiple vascular channels coalesce into one large

Figure 18 MRA of an AVM prior to stereotactic radiosurgery. (a) The phase contrast angiogram (velocity encoding = 80 cm s^{-1}) demonstrates enlargement of the right pericallosal artery (arrow). (b) A second phase contrast angiogram (velocity encoding = 20 cm s^{-1}) reveals deep venous drainage into the vein of Galen. Cortical venous drainage along the medial aspect of the right parietal lobe is also noted (arrows). (c) Following the phase contrast angiograms a 3D time-of-flight acquisition was obtained. The axial projection demonstrates the pericallosal feeder to the AVM, as well as the AVM nidus (arrows)

venous structure. The ability to define the size and location of the AVM nidus is essential for the proper selection of patients for surgery, endovascular therapy, or focused radiation therapy.

For patients with AVMs, the MR angiographic evaluation attempts to (1) identify the arterial supply to the AVM (Figure 18), (2) determine the size and location of the AVM nidus, (3) define the location and morphology of the venous drainage (Figure 19), (4) identify high flow aneurysms, and (5) attempt to detect the presence of fistulas within the AVM. The patient is initially evaluated by obtaining spin echo images. Typically sagittal T_1 -weighted and axial fast spin echo T_2 -weighted images are obtained. Sagittal 2D phase contrast angiograms are acquired with multiple velocity encodings (e.g. 80 and 20 cm

(a)

(b)

Figure 19 Occipital lobe AVM. (a) The phase contrast MRA study demonstrated an enlarged angular branch of the middle cerebral artery and enlargement of the right posterior cerebral artery. There are dilated cortical veins overlying the vascular malformation, with superficial venous drainage extending into the transverse sinus (arrow). (b) The 3D time-of-flight study was obtained without intravenous contrast material. The nidus of the vascular malformation is identified (arrow) and the posterior cerebral and middle cerebral artery feeders are clearly delineated

s^{-1}). By generating images that emphasize fast and slow velocities it is possible qualitatively to assess blood flow within the AVM. Additional advantages of this approach are that the arterial supply is well defined at the higher velocity encodings

and the venous drainage is delineated at the lower velocity encodings. High flow rates may also be quantitated by cine phase contrast MRA techniques.

6.3.3 Intracranial Aneurysms

MRA is also becoming an important modality for identifying and characterizing intracranial aneurysms. Although MRA has outstanding potential as a noninvasive method for identifying intracranial aneurysms, the present limitations of MRA require that it be used cautiously in this patient population. Failure to detect an intracranial aneurysm may result in inappropriate therapy and subsequent devastating subarachnoid hemorrhage. The identification of intracranial aneurysms prior to hemorrhage is of critical importance because nearly half of all patients presenting with acute subarachnoid hemorrhage will die within the first 30 days of rupture.

Although the morphology of intracranial aneurysms is best delineated by 3D time-of-flight MRA, additional information regarding the flow dynamics of the aneurysm can be obtained by using phase contrast techniques⁵⁷ as shown in Figure 20. A useful approach is to obtain a 2D phase contrast angiogram in a plane that profiles the aneurysm and parent vessel. This is conveniently done by reviewing a 3D time-of-flight angiogram. The velocity encoding of the phase contrast angiogram can be selected to emphasize the faster inflow jet or the slower circulating central vortex flow. Another advantage of the phase contrast angiogram is that high signal intensity thrombus does not appear in the angiographic image, thus better delineating the residual lumen. In addition, time-resolved cine phase contrast angiograms can be acquired to define variations in the size and configuration of the aneurysm during the cardiac cycle (Figure 21). Occasionally, a portion of the aneurysm wall will bulge during systole, suggesting that this portion of the aneurysm wall may be more likely to rupture. Thus phase contrast

(a)

(b)

Figure 20 Giant middle cerebral artery aneurysm. (a) The axial 2D phase contrast MR angiogram demonstrates slow vortical flow within the aneurysm (velocity encoding = 20 cm s^{-1}). (b) The axial 3D time-of-flight angiogram displays only the high velocity inflow jet (arrow); the slow flow within the aneurysm is not visible due to saturation

(a)

(b)

Figure 21 Change in aneurysm size during the cardiac cycle. (a) The cine 2D phase contrast image was obtained during systole and represents one of 16 images obtained during the cardiac cycle. Note the high signal intensity inflow jet (arrow). (b) During diastole the slow flow along the wall of the aneurysm can be appreciated (arrow)

MRA plays an important adjunctive role in 3D time-of-flight MRA for the presurgical workup of patients with intracranial aneurysms.

6.3.4 Cerebral Venous Thrombosis

Complex difference 2D phase contrast angiography is a fast and effective method for imaging blood flow within the dural sinuses. The phase contrast angiogram can be made sensitive to venous flow rates by selecting a relatively low velocity encoding (e.g. 20 cm s^{-1}) as illustrated in Figure 22. Clinically useful images that clearly demonstrate the dural sinuses can be obtained in approximately 4 min. A midline sagittal phase contrast angiogram displays flow in the sagittal sinus as well as the internal cerebral veins, vein of Galen and straight sinus.

Phase contrast angiograms can also be obtained in the axial plane to detect flow in the lateral sinuses and jugular veins. In this projection, the confluence of the dural sinuses is well visualized as well as the transverse and sigmoid segments of the lateral sinus. Phase contrast angiography has several desirable features that favor successful imaging of the dural sinuses. Phase contrast angiograms are sensitive to flow in all directions facilitating imaging of complex geometries such as the sigmoid sinus. There is also better visualization of inplane flow due to the subtraction of background tissue. Most importantly, high signal intensity thrombus is subtracted from the flow image along with the other stationary soft tissues. The result is an MR venogram that is sensitive to slow flow and only displays moving blood.

7 CONCLUSIONS

Cardiovascular disease is the leading cause of death in the industrialized world. Consequently, considerable medical resources are employed each year in its diagnosis and treatment. Before the advent of magnetic resonance imaging, diagnosticians relied primarily on invasive X-ray methods to visualize vascular anatomy. Unfortunately, X-ray methods are uncomfortable and present a risk to patient health. A frequently used alternative to X-ray angiography is ultrasonic imaging. While ultrasonic methods are risk-free, they are limited to a few clinical applications, and are heavily dependent on the skill of the operator.

Magnetic resonance angiography has become an important imaging modality for the diagnosis of vascular disease because it overcomes many of the limitations of X-ray and ultrasonic imaging methods. For example, MRA presents the patient with the same degree of risk as conventional MRI. Unlike

Figure 22 Sagittal sinus thrombosis and recanalization. (a) The sagittal phase contrast angiogram obtained at a velocity encoding of 30 cm s^{-1} reveals absence of flow in the sagittal sinus and straight sinus (arrowheads). (b) The follow-up phase contrast angiogram obtained 1 month following anticoagulant therapy demonstrates recanalization of the sagittal sinus (arrowheads). There is, however, persistent thrombus within the straight sinus (arrow). Note that the inferior sagittal sinus is visible (open arrowhead)

ultrasonic methods, MRA is applicable to a wide variety of blood vessels within the body and does not require a highly skilled operator.

Magnetic resonance angiography has several features that make it more suitable than X-ray angiography for many clinical situations. For example, patients with compromised renal function may be better served with MRA since the injection of X-ray contrast media employed in X-ray angiography can cause renal failure. The absence of ionization radiation is an attractive aspect of MRA and is particularly important for pediatric applications.

Magnetic resonance angiography also provides information that is difficult or impossible to obtain with X-rays. In addition to providing cross-sectional images of blood vessels, MRA can provide details of blood flow dynamics and quantitative measurements of blood velocity. Perhaps the most significant aspect of MRA, however, is that the technology is still young and prospects for future development in applications and techniques are excellent.

Time-of-Flight Method of MRA

Gerhard Laub

Siemens AG., Erlangen, Germany

1 BASIC PHYSICS

Most of the techniques currently used for magnetic resonance angiography (MRA) are based on one of the following basic physical principles: time-of-flight and phase shift effects. Time-of-flight (TOF) is related to the macroscopic motion of spins with a different history into the imaging volume.^{1,2} Phase shift effects are based on the motion of spins along the directions of the magnetic field gradients which are used for the spatial encoding of the spins.^{3,4}

Both effects are incorporated into imaging sequences for the purpose of flow visualization. Figure 1 demonstrates the idea of inflow enhancement which is the basic effect for TOF MRA. The blood flow is assumed to be perpendicular to the imaging plane [or volume in the case of a three-dimensional (3D) study]. For repetition times shorter than the longitudinal relaxation time T_1 , the signal of tissue within the slice will be reduced due to partial saturation effects. Blood flow will move spins from outside the slice which have not been subjected to the spatially selective rf pulses into the imaging volume. These unsaturated or fully relaxed spins have full equilibrium magnetization and, therefore, upon entering the slice, will produce a much stronger signal than stationary spins assuming that a gradient echo sequence is applied to avoid outflow effects otherwise seen with spin echo sequences.^{5,6} This effect has also been referred to as the 'entry slice phenomenon'.

Figure 1 Principle of inflow enhancement. The longitudinal magnetization M_z of spins in the imaging slice is reduced due to partial saturation for $TR \ll T_1$. Inflowing spins have equilibrium magnetization M_0 and, therefore, will produce more signal intensity. The displacement of the spins for each TR interval is Δs

Figure 2 Relative signal enhancement of inflow enhancement as a function of blood flow velocity. As velocity increases, the signal gradually increases to reach a plateau beyond which no further signal enhancement occurs

A simple model helps to get a more quantitative aspect of inflow enhancement. According to Figure 1 a critical velocity v_{th} can be defined as

$$v_{th} = s/TR \quad (1)$$

Spins flowing at velocities smaller than v_{th} will see several rf pulses depending on their actual speed, and consequently, the longitudinal magnetization will decay. Accordingly, less signal will be produced. With velocities larger than v_{th} the spins will see only one rf pulse, resulting in maximal signal enhancement. The overall signal enhancement as a function of the spin's velocity is plotted in Figure 2.

The second flow effect, flow-induced phase shifts, is a consequence of the phase memory of the spin system. When traveling along the direction of magnetic field gradients, the excited spins will experience additional phase shifts which depend on the motion of spins. Techniques which make use of the flow-induced phase shifts are usually referred to as phase contrast MRA.^{7,8} In the case of TOF MRA phase effects are eliminated as much as possible by using a flow-compensated gradient waveform in combination with short echo times as shown in Figure 3. Both the slice select and the readout gradients are flow-compensated to minimize flow-induced phase shifts. The signal from blood flowing into the slice is maxi-

Figure 3 Typical timing diagram of a flow-compensated gradient echo sequence. Asymmetric echo sampling is used for shorter echo times

Figure 4 Four images acquired at different positions in the neck. A FLASH sequence with $TR/TE/\alpha = 30\text{ ms}/9\text{ ms}/40^\circ$ is used to saturate stationary spins in the slice and produce high signal from inflowing blood. Slice thickness is 2.5 mm with 0.5 mm overlap, and a total of 60 slices is acquired to cover a section of 120 mm of the neck vessels

mized by a proper selection of sequence parameters. In most cases a pulse repetition time TR of 30–40 ms along with tip angles of 40° results in sufficient saturation of biological tissues, as demonstrated in Figure 4. According to equation (1) thin slices help to avoid spin saturation within the slice in the case of slow blood flow. For a TR of 30 ms, and a slice thickness of 3 mm, a blood flow velocity of 10 cm s^{-1} is sufficient to replace all of the spins in the slice within one TR interval, resulting in good vessel/background contrast. Additional presaturation pulses are applied on either side of the slice to suppress either arterial or venous inflow enhancement.

2 POSTPROCESSING OF 3D DATA SETS

In principle, with this technique any vessel segment can be imaged by cutting through the vessel perpendicular to the flow direction. With repetitive increments of the slice position a 3D data set of the complete vessel tree can be measured. (see Figure 4 for example). For the observer, this form of representation requires experience in order to obtain the correct 3D spatial impression. Obviously, postprocessing methods should be used to extract two-dimensional (2D) projections of vessel structures from the 3D volume information. With these methods spatial impressions can be obtained in two ways: by showing a sequence of projective images with different projection angles, or by coding of the depth information onto the surface of the displayed objects.^{9,10}

Since the surfaces of most vessels are relatively small, the first method, multiple projections with different angles, has proven more useful in practice. The starting point for this method

Figure 5 Schematic representation of the maximum intensity projection (MIP) method

must be a 3D data set in which the structures to be extracted are associated with a characteristic range of signal intensity levels. In this case a projective image can be calculated by penetrating the data volume with a set of parallel projection rays and selecting along each of these rays only the data point that represents the intensity maximum as demonstrated in Figure 5. The inflow enhancement and proper pulse sequence parameters (flip angle, pulse repetition time, and flow compensation on) ensure that the maximum intensity is always associated with a blood vessel, as long as the projection ray intersects at least one. All of the other projection rays will just pick up a background pixel out of the 3D data set. As a result, Figure 6 demonstrates a complete projection image calculated from one 3D data set.

Figure 6 Calculated MIP from the 3D data set of the carotid artery. Sixty slices were acquired in sequential order and transverse orientation with 160×256 matrix and $3/4$ rectangular field-of-view. Total acquisition time was 4 min 48 s for all 60 slices

Figure 7 Three-dimensional fast FFT imaging techniques in TOF MRA. The whole volume of slab thickness D is excited by an rf pulse, and is then subdivided into N partitions by the use of an additional phase-encoding gradient. The contrast of blood vessels is maximal at the entrance plane of the imaging volume, and decreases constantly toward the exit plane due to spin saturation

By varying the projection angle multiple projective images can be obtained retrospectively which allow the observer to obtain the correct spatial impression of the 3D information. By displaying a number of projections with projection increments of only a few degrees in a rapid fashion, the impression of a continuously rotated object will be generated which allows a correct 3D visualization of such complex structures as a vessel tree.

Improvement of the spatial resolution along with an improvement of the signal-to-noise ratio can be achieved with 3D imaging techniques. As shown in Figure 7, the whole volume is excited simultaneously, and will then be subdivided into thin partitions or slices by using an additional phase-encoding scheme in the slice select direction. Unlike 2D imaging, where the slice resolution is defined by the excitation profile of the radiofrequency pulse, the slice resolution is defined by spatially-encoding magnetic field gradients and can be less than 1 mm. In 3D, or volume imaging, complete compensation of the flow-induced phase shifts is also necessary to avoid flow artifacts in the form of signal losses and ghosting.^{11,12} For this purpose flow compensation is applied in conjunction with short echo times similar to 2D techniques.

The acquisition time T_A for a 3D data set is defined as

$$T_A = TR \cdot N_p \cdot N_s \quad (2)$$

where TR denotes the pulse repetition time of the sequence, and N_p , N_s are the number of phase-encoding steps in the phase-encoding and slab select directions, respectively. In most of the clinical protocols the repetition times vary between 20 and 40 ms and the typical matrix size is 192×256 with a $\frac{3}{4}$ rectangular field of view and 64 partitions along the slab select direction, resulting in acquisition times of between 4 and 8 min.

One of the major limitations of 3D TOF MRA is the loss of vessel contrast as spins penetrate into the imaging volume. This effect is due to progressive saturation when spins experience the rf excitation pulses in the imaging volume. As can be seen from Figure 8 the transverse magnetization decreases with the number of rf pulses, and the difference between blood and stationary tissue is reduced rapidly. A more effective use of the magnetization is possible when using variable flip angles across the slab.¹³ At the entrance plane when spins enter with equi-

Figure 8 Transverse magnetization of spins as a function of rf pulses. For constant flip angles throughout the imaging volume there is a constant decrease until the magnetization has approached its steady state value. In the case of a variable flip angle the signal reaches its maximum after about 12 excitations. As a result the contrast of blood is maintained over a longer distance in the imaging volume. Stat = stationary

librium magnetization a relatively small flip angle of, for example, 10° will still provide sufficient signal, without reducing the longitudinal magnetization too much. Next, the flip angle is increased a little to maintain, or even increase, the signal from blood spins on their way through the volume, and so forth. In principle, it is possible to shape the flip angle distribution over the entire imaging volume according to the specific flow velocity and vessel coverage.

A further improvement is possible by the application of magnetization transfer pulses (magnetization transfer contrast, MTC).¹⁴ The idea is to use off-resonance rf pulses which do not directly affect the mobile protons which usually create the signal in MRI. Protons with restricted mobility, however, do get saturated, and because of magnetization or chemical exchange processes some of the magnetization will be transferred in some biological tissues, such as gray or white matter, resulting in a partial saturation. Blood will not be affected by the MTC pulses, and as a result, there will be more contrast between blood and background. This technique is particularly useful in the brain as demonstrated in Figure 9, as the background signal from gray and white matter tissue is significantly reduced.

3 DISCUSSION

The results of preliminary clinical studies indicate that this MRA technique can provide accurate, reproducible flow images in different anatomical regions of the body.¹⁵ Applications of TOF MRA for the assessment of intracranial vascular disease in the brain are shown in Figure 10. This technique is noninvasive and can be performed in conjunction with 2D spin echo or

Figure 9 Maximum intensity projection image of the intracranial vasculature. The images were acquired with a 3D FISP sequence including MTC partial saturation and TONE ($TR/TE/a = 40 \text{ ms}/6.5 \text{ ms}/10\text{--}30^\circ$). Total scan time was 8–20 min

gradient echo imaging, with only a 5–10 min extension of the examination time.

The unique advantages of this technique include the capacity to provide multiple projections of anatomically complex vascular abnormalities with a single data acquisition. It appears

that this capability may increase both the sensitivity and the specificity of MRA in some patients with cerebrovascular disease when MRA is performed in conjunction with routine spin echo imaging of the brain. While the acceptance of the 3D inflow MRA technique will depend on its sensitivity and specificity in disease diagnosis, as determined by means of prospective clinical trials relative to other screening modalities, the preliminary clinical results suggest that this MRA technique can serve as a screening tool for the identification of normal vasculature as well as stenosis and/or occlusions produced by atherosclerotic disease. It can be performed in conjunction with MRI of the brain, with only a small increase in examination time, and provides both vascular and parenchymal evaluation of cerebrovascular disease in a single setting.

Whole Body Magnetic Resonance Angiography

E. Mark Haacke, Weili Lin, and Debiao Li

Washington University, St. Louis, MO, USA

1 INTRODUCTION

The first seeds of whole body magnetic resonance began with the simple concept of spatial encoding using gradients in Paul Lauterbur's seminal 1973 paper.¹ It only took several years for it to be implemented on systems large enough for the human body, and developed rapidly owing to the several decades of previous study in chemistry and physics. Many of the concepts from steady-state free precession² to adiabatic fast passage³ would play a role in the understanding of how to deal with motion [usually of blood, but equally simply cerebrospinal fluid (CSF) flow] during a magnetic resonance experiment. The key to the present day success of MR angiography (MRA) lay in the discovery of how moving spins could be motion compensated.⁴⁻⁸ The advent of faster and faster computers and the role of image processing were key to the advances in MRA.⁹ Although the basic concepts of magnetic resonance whole body flow imaging are well understood today, there is still room for basic evaluation and applications from the biological to clinical sciences.

In this short article on whole body flow imaging, we will review the history behind bulk flow studies in the eras of pre-imaging and during imaging to show how technological and scientific advances led to the formation of dealing with motion as we understand it today. We begin by studying the effects of motion on the signal in terms of amplitude and phase, how it could be dealt with or corrected, the ongoing debate of whether phase contrast or time-of-flight (TOF) imaging is to be preferred, and what future directions remain to be investigated. This overview should serve as a good introduction to the more technical aspects of each of these areas.

2 THE EFFECTS OF MOTION

The first measurements and theory for magnetic resonance were based on the assumption that the spins were stationary. It was several years before the issues of motion were first addressed by Suryan¹⁰ in 1951, and several more years before the flurry of papers appeared in the mid-1950s on diffusion.¹¹ At this time a real effort was made to incorporate the effects of diffusion on the signal measured, and it was not long before the theory for the equations of motion were modified to deal with these phenomena.¹² Bulk effects in blood were considered toward the end of the decade by Singer¹³ and Bowman,¹⁴ who could be credited with the first TOF magnetic resonance experiments on blood. This TOF effect relates to the fact that the inflowing blood appeared brighter than it would have had it remained in the excitation region, and, hence, it was viewed as

having an effective T_1 smaller than that of stationary blood. It must be remembered that all the experiments evaluating the signals were from projections over the entire excited region (whether it was a small vial of material or a mouse tail) and that no imaging per se was done at that time. This fact had severe consequences on the subsequent development of flow methods and the ability to assess accurately what was happening. Nevertheless, brave attempts were made to detect and quantify flow. The effects were well enough understood from the amplitude changes that it was possible to design a flow-meter using magnetic resonance equipment.¹⁵

Two papers have significant historical relevance. The first is that by Hahn in 1960, where he recognized the fact that motion through a gradient would lead to phase dispersion at the echo.¹⁶ For a simple bipolar pulse (peak gradient amplitude, G , negative lobe of duration τ , positive lobe following of duration τ , constant velocity flow v) the phase at the echo is $\gamma G v \tau^2$ where γ is the gyromagnetic ratio. The key points to extract from this simple formula are the linear behavior with v and the quadratic behavior with time. The second key paper in retrospect is that of Packer¹⁷ in 1969 (later rediscovered by Waluch and Bradley¹⁸). He investigated the signal behavior when multiple pulses were used in the presence of gradients. He discovered the most important fact that the flowing spins rephased at the even echoes. This was the precursor to future imaging papers which rediscovered this phenomenon⁴⁻⁸ and others which extended the concept to correct for the fact that motion during the gradients led to a phase change. The first was subsequently revisited in the imaging world by Moran¹⁹ in 1982 and the second by Constantinesco⁴ in 1984. These two papers set the foundation for future advances in the field of MRA.

2.1 Time-of-Flight Effects

Early experiments with spin echo imaging noticed the 'flow void' effect or lack of signal from blood. This was at the time considered anomalous (or paradoxical) enhancement since blood has a spin density of 0.8 relative to water. It was quickly realized that those spins that did not see both the 90° and 180° pulses were not refocused and did not contribute to the signal. This is known today as the wash-out effect, and it depends very much on the direction of the flow relative to the slice acquisitions and the flow rate itself. The same phenomenon using gradient echoes leads to a wash-in effect where stationary tissue is saturated and inflowing blood is brighter than naively anticipated. This concept dominates today for much of MRA methodology to enhance the signal from moving blood. For a fast (short TR) gradient echo sequence, when a 2D slice or plane is excited, blood which was excited flows out of the slice and sees no more rf pulses during the experiment (or at least we will assume so, an assumption which is usually valid). For 2D imaging and constant blood flow, the blood will be imaged at the same location in each case. The signal seen will then be a sum over all sections of the blood each of which has seen a different number of rf pulses. For a 3D scan, the signal will be that of the blood in a given section which has seen that number of rf pulses associated with the time from its entry into the 3D volume and the repeat time.²⁰ Specifically, the number of rf pulses is $n = [t/TR]$ where $t = d/v$ with d the distance traveled, v the speed and $[]$ the integer part of the argument.

For blood which flows through the entire slice, each new rf pulse excites unsaturated or fresh blood, and hence this blood has the maximum possible signal. For a flip angle of 90° , the signal is a maximum at 1.0 units relative to the spin density of the blood. Figures 1 and 2 show the expected signal response for two different T_1 values for blood, the first of 1200 ms for pristine blood and the second for 300 ms for blood doped with a sufficient amount of T_1 reducing contrast agent. From these curves we see two most important features for imaging blood. The first is that at low flip angles of about $15\text{--}20^\circ$ the best contrast between blood and stationary tissue is achieved at 1.5 T even for fairly slow flow (hence most TOF imaging in the head is done with these low values). The second is that the use of contrast agents can dramatically enhance the contrast between even stationary blood and background tissue (assuming that gray matter is the background tissue with a T_1 of about 950 ms at 1.5 T, quite close to that of blood).

2.2 2D versus 3D TOF

From the above arguments, it is clear that thin slices are best to obtain maximum signal for slow flow²¹ (for example, with $TR = 40$ ms and a 2 mm thick slice, flow greater than 5 cm s^{-1} presents with a maximum signal). This is still considered the best way to image veins in the leg.²² In these images, both arteries and veins will be bright. To avoid confusion between the two, a saturation pulse is usually applied upstream to saturate arteries or downstream to saturate veins (the latter is used when imaging the carotid arteries in the neck). However, 2D TOF suffers from longer echo times (although some cures for this may exist through higher gradient strengths²³ or rf design²⁴), and a longer acquisition time for thin slices due to the need to overlap slices for full spatial coverage. Saturation pulses can saturate retrograde flow, and through-plane resolution is not as good as a 3D acquisition. On the other hand, slow flow is easily seen and a small region of interest can be rapidly covered. The use of 3D imaging overcomes many of the above problems as it allows for short echo times and thin contiguous slices. It has the problem that blood appears nonuniformly throughout the region of interest because of the spin saturation. This is partly overcome using a variable flip angle spatially²⁵ (obtained by applying an rf pulse designed to increase along one direction, usually the direction of flow, so that saturation effects are reduced; this method is referred to as TONE or tilted optimized nonsaturating excitation), multiple thin slabs,²⁶ magnetization transfer saturation or MTS,^{27,28} and contrast agents.^{29,30} The use of MTS is good because it does not require injection of a contrast agent and it can suppress the background brain parenchyma^{27,28} by about 25% or myocardium³¹ by up to 50% while leaving the signal from blood virtually intact. MTS pulses have two problems: they add more power deposition to the sequences so care must be taken in their design and implementation, and they do not suppress lipid signal. The advantages of using a contrast agent are that the scan can be run faster, or better resolution can be obtained, or a larger field-of-view (FOV) can be obtained without saturation effects. The problems are that both arteries and veins become bright, and the signal from regions of the blood-brain barrier breakdown can obscure vessel information; for both these reasons, vessel tracking is needed^{32–34} to separate the vessels of interest from other vessels or tissues.

Figure 1 Blood signal as a function of flip angle for different numbers of rf pulses (n) for $T_1/TR = 24$

2.3 Phase Effects

The presence of motion during the application of a gradient pulse causes a phase shift of the signal from the moving tissue at the echo. For a simple bipolar pulse of duration and amplitude G , the phase is simply $\gamma G v t^2$ where v is the speed along the direction of the gradient G . In fact, for any symmetrically placed gradient pulses about a 180° pulse at time t' [i.e. a time reversed pulse where $G(t') = G(2t' - t)$ for $t > t'$], the phase for constant velocity spins will be zero at $t = 2t'$. This shift in phase is not necessarily a problem. For constant velocity plug flow for every phase encoding step (where the flow is only along the read direction), the final image in the region of the flow will have a nonzero phase as described above and the correct amplitude on a magnitude image. In practice, for nonpulsatile laminar flow, spins develop a different phase as a

Figure 2 As in Figure 1 but for $T_1/TR = 6$ for blood with a triple dose of gadolinium diethylenetriaminepentaacetic acid (Gd-DTPA)

function of position, and the signal in a voxel is reduced accordingly. For example, in a 1D analogy, if the flow varies linearly across a voxel, the signal will be reduced to $(\sin \theta)/\theta$ of its original value for a phase dispersion of 2θ . For a phase dispersion of 180° , the signal will fall to $2/\pi$ of its initial value (only a 30% signal loss). Both velocity and acceleration can create large velocity gradients in blood flow (in areas near stenoses or curved flow). Interestingly, the loss of signal has been recognized quite early, and in spin echoes was partly due to the outflow of the blood between the 90° and 180° pulses, and created a flow void. Today the dephasing and in-flow/out-flow phenomena are also used to create what are referred to as 'black blood' images. These are often very useful in delineating vessel wall. The disadvantage of this method is the poorer contrast-to-noise ratio of blood versus background in rapid imaging. The inflow enhancement (wash-in effect) of the bright blood methods offers a potentially much higher contrast-to-noise ratio between vessel and surrounding tissue.

Even for plug flow, phase is a problem if the flow is pulsatile. Now the phase changes from line to line and creates what is referred to as ghosting. This can be understood as a periodic change in signal which creates a periodic effect on the sampling and hence creates aliasing of the image. The graphs Figures 1 and 2 indicate how severe a problem this is when the flip angle is large, as now the signal jumps rapidly depending on how many rf pulses the blood sees (and therefore on how fast the blood is flowing²⁰). Clearly, this problem is avoided at low flip angles where the signal becomes more spin density weighted and the differences in flow are less observable.

Pulsatility can be handled quite well by triggering off the cardiac cycle. Now if a bipolar pulse is added to a conventional sequence and G is chosen so that the phase changes by less than π for all velocities, it is easy to use just the phase image to determine the blood velocity in the direction of the gradient. In principle, three such experiments must be run to determine the full velocity vector. It then becomes possible to predict from the sequence structure and the geometry how many rf pulses would be seen during the experiment and therefore what the magnitude of the signal should be. This would allow for a self-consistency check between phase and magnitude of the images. Little work has yet been done in this direction, although when it is accomplished it will have brought together the initial historical focus on amplitude flow imaging discussed in the introduction with the flow quantification efforts begun after the advent of MRI.

3 MOTION COMPENSATION

The real beginnings of MRA came with the recognition that there were effects on the signal from flow. These were only brought under control by the redesign of the gradient structure to fix the phase at the echo to be zero even in the presence of motion. First-order motion compensation refers to compensating for constant velocity flow⁴⁻⁸ so that the phase at the echo is zero. This is effected by using at least three gradient lobes in both the read and slice select direction so that the zeroth and first moment of the gradients is zero at the echo. Higher order terms such as acceleration and jerk are then usually not zero (although even order terms can be in some cases^{35,36}). The choice of timings and

amplitudes makes this a complicated optimization problem.³⁷ It has been suggested²⁰ and shown^{38,39} that the best choice to make in the design of these sequences when acceleration effects are present is to keep the duration of the gradients as short as possible. In an uncompensated sequence, acceleration effects grow as time cubed, but in a velocity compensated sequence they grow as only time squared. This is still fast enough to warrant collecting the data with an asymmetric echo⁴⁰ rather than adding a fourth pulse and compensating for acceleration as well. In summary, the sequence is designed so that

$$\int_0^{TE} G_r(t) dt = 0 \quad (1)$$

and

$$\int_0^{TE} t G_r(t) dt = 0 \quad (2)$$

for the readout gradient, G_r and

$$\int_T G_{pe}(t) dt = T \Delta G_{pe} \quad (3)$$

and

$$\int_T t G_{pe}(t) dt = 0 \quad (4)$$

for the phase-encoding gradient.⁴¹ Here, T is the time from the beginning of the first phase-encoding table to the end of the second phase-encoding table, and G_{pe} is the usual phase-encoding increment.

An example 3D sequence which has partial motion compensation in all axes is given in Figure 3. This sequence is ideal for phase-encoding in that it also compensates for position shift or spin misregistration. For example, since the phase encoding gradient is shifted temporally from the echo, the spins are encoded at a different location than they are read out at and, therefore, they appear shifted in the image from their actual location. (This gives the appearance of a black hole where the vessels should have been and the vessels appear extra bright because they now lie on top of some other tissue—a fact which has ironically proved useful for visualizing vessels.) By velocity compensating in the phase-encoding direction as discussed above, there will be no misregistration artifacts; an important point if the magnetic resonance images are to be used as a reference for neurosurgical applications.

4 FLOW MEASUREMENT

The observation of flow is quite a different challenge to its measurement. Early attempts to measure flow rates used the effective change in T_1 , as the faster the flow, the less saturated it was and hence the shorter the effective T_1 . These amplitude approaches rarely proved useful. The concept of flow to visualize and quantify blood flow also began rather early. In 1959, Singer described a method of quantifying blood flow in a mouse's tail by using a receiver downstream of the transmit-

Figure 3 A 3D sequence diagram showing velocity compensation at the echo in both read and phase-encoding directions. The slice select tab file could have added to it a second tab file and the partition encoding could then be velocity compensated. *FE* refers to the time from the onset of the read gradient to the echo. *ADC* refers to the analogue to digital conversion of the signal to finite sampled data during the acquisition period

ter.¹³ The time delay between the spin excitation and signal reception was used to measure the flow velocity. The method was then further modified and applied to human arms and fingers.^{42,43} It was used again in imaging for adiabatic excitation of inflowing blood⁴⁴ and for exciting and refocusing just blood using a 180° pulse (orthogonal to and in the direction of the blood flow) in a spin echo experiment.^{45,46} This gave an image showing how far the blood had moved between its encoding after the 90° pulse and where it was finally read out. For laminar flow, the fastest flow moved furthest into the image, and the standard crescent shape was seen in this type of image. The same type of approach was later implemented using fast imaging sequences by employing a saturation pulse instead of a 180° pulse.⁴⁷ Although this is well described as part of the same concept, in retrospect one did not follow on the heels of the other but was rediscovered from a different perspective when saturation pulses were used to eliminate signal from unwanted tissue. By nulling the blood before the conventional excitation pulse and acquiring the data in a cardiac triggered mode, the saturated blood could be followed throughout the cardiac cycle. The complement of the bright blood image using the spin echo approach was seen with the crescent shape now being dark. Another variant of this method can be used to create a bright bolus of blood by using a magnetization preparation type of sequence to null or reduce the signal from the background tissue and then dynamically to acquire the data

throughout the cardiac cycle or just continuously to watch the inflow of blood. This is best accomplished using a rapid 2D acquisition approach such as a short *TR* method or echo planar imaging with blood inverted outside the slice. In these cases, the blood signal changes from negative to positive as time progresses and the longitudinal magnetization recovers (this approach is limited by the T_1 of blood to a few seconds).

4.1 1D Velocity Information

One of the concerns about MRA is that it does not give functional information. In this section, different methods of giving velocity information are discussed. One method projected to give velocity information quickly is the Fourier flow quantification technique first introduced by Moran.¹⁹ He recognized that because of the linear dependence of the phase on the velocity and the gradient that a set of experiments changing the strength of an applied bipolar gradient, for example, would phase encode the velocity in that direction. Collecting in a 1D velocity and 1D transverse spatial direction through the neck gives a nice display as a function of the cardiac cycle of the different positive and negative velocity components in all the vessels cutting across the excited region.⁴⁸ The resulting image shows velocity versus position with the amplitude of the signal representing the number of spins at that location with that velocity. This can also be accomplished in a much simpler way by exciting just a plane⁴⁹ or cylinder⁵⁰ and projecting all information along the read axis. The flow is then sensitized to one direction (usually along the slice select direction using the bipolar gradient scheme discussed earlier), and the phase is used to map directly the velocity of all spins summed over the projection. This is often used in the aorta or to see heart valves in motion. It can have a time resolution of 20 ms and does not require cardiac triggering. It has difficulties if arteries and veins overlap as vessel phase data become confounded. We will return to this method in the future directions section.

4.2 2D or 3D Phase Contrast Imaging

The most common and best investigated approach to flow quantification today is phase contrast imaging pioneered by Dumoulin.^{51,52} By not fully compensating the blood motion, a remnant phase remains which is proportional to the velocity. Using a sequence with one bipolar pulse giving a positive phase and a second sequence with a polarity inverted bipolar pulse giving a negative phase, the subtraction eliminates stationary tissue and leaves tissue with a nonzero velocity. This is the conventional approach used in 2D imaging and goes back to the early work of Moran¹⁹ and, somewhat later, Bryant.⁵³ However, the bipolar pulse can be applied in all three directions and not at all so that the experiment is repeated four times and full 3D velocity information can be extracted. If the gradient amplitude chosen is too small, aliasing of the phase will occur. If the resolution is high enough, the aliasing can be unwrapped, but this is rarely done today (because of the processing time and difficulties in passing through or around regions in the image with no signal and because the phase is complicated by field inhomogeneity phase effects in gradient echo imaging). This is actually the best way to collect the data in terms of the signal-to-noise ratio (S/N) as a higher phase has a higher S/N. Phase contrast images can be acquired in two or

three dimensions. Their main disadvantage is the length of time it takes to acquire information in all three directions and the fact that this is a necessity. 3D phase contrast imaging is less sensitive to inflow but still loses signal from the saturation phenomena. Nevertheless, small vessels with very slow flow (much less than 5 cm s^{-1}) can be seen quite well with this approach, as can CSF.⁵⁴ Today the use of 2D phase contrast imaging is the most common to obtain flow rates by using the velocity information orthogonal to the excited plane and a high-resolution cross-section for the vessels. Since many pixels should be available for a given area, this limits its application to vessels with diameters several times the available pixel size. A further limitation comes from the fact that a fixed maximum phase is usually encoded for, so that any values of velocity above this maximum lead to aliasing in the image. This implies that, if there is a broad range of velocity information present, several scans would need to be run to obtain the optimal S/N.⁵⁵

5 MRA OF THE ENTIRE BODY

5.1 Contrast Optimization

Both TOF and phase contrast methods need to be optimized depending on the regions being imaged. The optimization is not just one of getting the best S/N, but rather the best contrast-to-noise ratio or, one step further, object visibility. Phase contrast offers the best suppression of background tissue and the best S/N when the subtraction of two phase images is performed. The lower velocities are the hardest to see as the image intensity is proportional to the velocity. Nevertheless, phase contrast can do a good job with slow flow if the gradient causing dephasing is made very large. It does suffer from velocity changes in time (pulsatility) which causes ghosting (except in a cine mode where the images are gated to the cardiac cycle). TOF can give good contrast in a variety of ways. These will be discussed individually in the different body part discussions to appear below. Suffice it to say at this time that the major improvements in this approach come from magnetization transfer contrast and the use of contrast agents.

Lastly, there are other contrast mechanisms available such as black blood^{56,57} and steady-state free precession imaging (to map the tissue properties of blood rather than its flow⁵⁸). In the latter case the challenge is to make the signal insensitive to the flow and then using spin density or T_1/T_2 to recognize blood from background tissue. In this section we will address the different areas of the body presently covered by MRA applications.

5.2 Head and Neck MRA

Currently MRA is most widely used for imaging the head and neck. Nevertheless, as mentioned above, there still remain problems. The four most dominant ones include: loss of signal from disturbed or very fast flow (such as in regions of curved flow or tight stenoses); spin saturation caused by stationary blood or very slow flow (such as for obstructed flow or flow in the carotid bulb, for example); insufficient resolution (such as in the intracranial or carotid bifurcation studies to verify accurately if a stenosis is 75%

or higher; and an insufficient S/N (for when high resolution is used). Solutions to these problems are still under development, and for the previous four points include: the use of shorter gradient timings to generate the echo; the use of spatially varying (or TONE) pulses, MTS, fat saturation and contrast agents to improve the contrast-to-noise ratio; the use of a smaller FOV or partial Fourier reconstruction methods to improve resolution; and the designing of new coils and, again, the use of contrast agents for a better S/N. Fat saturation itself has been a major problem since it requires a very uniform field to avoid saturating water instead. Without the use of segmentation methods fat otherwise blocks information in a maximum intensity projection (MIP) because of its remnant high signal (especially after the use of an MTS pulse, which suppresses gray matter/white matter in the head or muscle in the neck). Some other methods are also under development which will use many of the above improvements but whose purpose is to get 'black blood' images for highlighting vessel wall to examine plaque with high resolution and a spectroscopic analysis, as well as methods for functional imaging to see dynamic local blood flow with and without contrast agents. Ideally, one would like to cover a large region of interest very quickly, but this usually leads to blood saturation. The combination of the above methods would make it feasible to cover the entire head or neck in 5–10 minutes. At the moment the high contrast and high resolution aspects are accomplished using the multiple thin slab method in a transverse orientation.

This latter method, the use of the MIP algorithm, and the use of contrast agents all also require the use of vessel tracking or blood segmentation postprocessing to extract the best representation of the blood vessels from the images. The multislab technique requires significant overlapping of adjacent 3D slabs because of the tapering off of the rf profile at the slab edges. Using segmentation it becomes possible to extract the vessels from the background in most slices even given the spatial variation of signal intensity, and to digitize the images. Merging the newly processed data now eliminates the border artifacts otherwise evident in the final MIP images (Figure 4). The MIP itself causes a loss in the contrast-to-noise ratio, but if applied to the segmented data over a dilated region about the vessel tracked information this becomes less of a problem and, in fact, opens the door to other types of projections such as a straight sum, for example. These methods are becoming automated, so that the user only needs to input a single seed point in most cases [this is true for the major vessels in the head (Figure 5) and neck (Figure 6), and even for the cardiac system]. Other types of displays such as surface or volume rendering can also be used to advantage, and these will be dealt with in other sections in this treatise.

5.3 Cardiovascular Imaging

The application of MRA techniques to the heart is relatively new compared to that in the head and neck, owing to the special challenges and technical difficulties in magnetic resonance flow imaging of the heart. The motion of the heart during cardiac and respiratory cycles is the major obstacle for consistent magnetic resonance images. Some kind of motion compensation is usually needed to overcome this problem. Prospective or retrospective electrocardiogram (ECG) triggering is

Figure 4 Intracranial study with a high-resolution two slab acquisition (a) without and (b) with vessel tracking. The MIP has obscure information in (a) which is brought out after vessel tracking in (b). The image parameters were: $TR = 35$ ms, $MAT = 160 \times 256$ with a $5/8$ rectangular FOV, $FA = 15^\circ$ and slice thickness = 1 mm with 64 partitions

used in almost all imaging cases to obtain cine images (images obtained throughout the cardiac cycle one after the other) or to minimize the cardiac motion effects. The respiratory motion effects are usually reduced or eliminated by prospective or retrospective respiratory gating, multiple signal averaging, or breath-holding. The major areas of magnetic resonance flow imaging application in the heart include the coronary arteries, great vessels, cardiac chambers and valves.

5.3.1 Coronary Arteries

In addition to their movement, coronary arteries have a small size. Thus, a high S/N and spatial resolution are required to visualize the coronary arteries reliably. Further, the coronary arteries are surrounded by epicardial fat, which tends to have a strong signal. Some kind of fat saturation is needed to increase the conspicuity of the coronary arteries. Early attempts at coronary MRA used multislice, multiphase, spin echo,⁵⁹ 2D gradient echo cine,^{60,61} and inversion-recovery techniques.⁶² Recent efforts have been on segmented 2D gradient echo acquisition,^{63,64} fast spiral echo planar acquisition,⁶⁵ and 3D acquisition.⁶⁶⁻⁶⁹ 2D scans are usually acquired within a single breath-hold, thus eliminating the respiratory motion effects. However, 2D images have relatively thick slices and evaluation

Figure 5 Comparison study of the intracranial vascular system (a) without and (b) with the contrast agent Gd-DTPA. A single dose of 0.1 mmol kg^{-1} was used. Saturated slow flow blood is now enhanced, especially for smaller vessels

of images may be complicated by the discontinuity of the slices acquired from different breath-holds since coronary arteries are highly tortuous. The acquisition of the 2D images also requires more patient cooperation and experience from the operator. Fast 3D scans with fat saturation create thin and contiguous slices, and can be easily postprocessed to visualize the coronary arteries (Figure 7). 3D scans have a better S/N and higher resolution than 2D images, and do not require breath-holding. However, image blurring will occur, reducing the effective resolution. Both hardware (echo planar system,

Figure 6 High resolution carotid artery study (a) without and (b) with vessel tracking. The imaging parameters were: $TR = 31$ ms, $TE = 7$ ms, $FA = 20^\circ$, $MAT = 256 \times 512$ and $TH = 1$ mm

high/faster gradient capability, better coils, respiratory gating) and software advancement (sequence development and postprocessing such as retrospective respiratory gating^{70,71}) will further improve the performance of coronary MRA. These improvements will lead to faster coronary artery imaging using 3D retrospective^{72–75} or 3D breath-hold^{76–79} techniques and greater coverage of the heart.

Using a segmented gradient echo sequence, Burstein first reported on the feasibility of measuring coronary artery flow in isolated and in vivo hearts.⁸⁰ A phase contrast modification of this method allowed quantification of the coronary artery flow velocity within a breath-hold.⁸¹ TOF quantification of the coronary flow with echo planar imaging was demonstrated to provide real time cine images.⁸² Currently the spatial resolution of these techniques is still not adequate for accurate blood volume and, therefore, blood flow calculation.

5.3.2 Great Vessels

The anatomy of great vessels can be demonstrated by spin echo images.^{83,84} The blood is dark due to wash-out effects, and the vessel wall is highlighted. 2D and 3D TOF MRA sequences have also been used to evaluate the great vessels. Common great vessel diseases include dissection and congenital diseases. 3D sequences may have the advantage when complicated vascular abnormality is involved because of the postprocessing capability of 3D images. Cine phase contrast methods are commonly used to evaluate the blood flow in the aorta.^{85,86} Blood flow information is important to study the

flow patterns and to evaluate the functional significance of great vessel diseases. The same methods were also used to assess the vena caval flow.⁸⁷

5.3.3 Cardiac Chambers and Valves

Cine gradient echo sequences have been used to visualize the cardiac pools to evaluate cardiac function.⁸⁸ Magnetization transfer saturation is applied to enhance the blood/myocardium contrast.⁸⁹ Cardiac parameters such as ejection fraction, stroke volume, and cardiac output can then be calculated from the images. A segmented gradient echo sequence was also used to acquire cine images within a breath-hold to eliminate the motion of the heart induced by respiration. Signal void jets in the cardiac pools may indicate abnormalities of valves such as regurgitation and stenosis. Phase images of the cine scan can provide additional information about the motion of blood and myocardium during the cardiac cycle. Specifically, jet velocity mapping was used to assess valve stenosis.⁹⁰

5.3.4 Pulmonary Arteries

Pulmonary artery flow imaging is a difficult task because of motion, magnetic susceptibility variations due to air–tissue interfaces in the lung, and the overlapping of arteries and veins. TOF gradient echo techniques are used in imaging the pulmonary vasculature. 2D scans are run within a single breath-hold.^{91–93} These images have an enhanced blood signal due to adequate inflow and minimum motion artifacts.

A 3D syncopated sequence was proposed^{91–94} to visualize the pulmonary vasculature. Multiple signal averaging is used to eliminate the ghosting artifacts due to motion and demonstrate the location where vessels stay most of the time. By adding an inversion pulse before data acquisition, a ‘black blood’ scan is obtained. A combination of ‘bright blood’ and ‘black blood’ scans will be able to differentiate normal blood and emboli, which should have high intensity in both scans. The advantage of 3D imaging is that the images can be postprocessed by MIP to evaluate the whole vasculature. An example MIP image generated from an ECG-triggered 3D ‘bright blood’ scan is shown in Figure 8.

Patients with a single lung transplantation are studied using phase contrast velocity mapping.⁹⁵ The blood volume and flow pattern of the native and transplanted lungs are compared and could be used to monitor these patients.

5.4 Renal Arteries

Image artifacts associated with cardiac, respiratory, and bowel motion, and the inherent complex flow patterns and directions of the renal arteries are the major challenges for renal artery flow imaging. Reasonable success has been achieved in imaging the renal arteries using both 2D^{96–99} and 3D phase contrast methods.¹⁰⁰ These methods are sensitive to slow flow and can achieve good background suppression. However, they are sensitive to pulsatile and nonuniform flow and tissue motion, and are time consuming.

2D TOF methods^{96,101} have been applied to acquire MRA images of the renal arteries with breath-holding. The major problems with these techniques are the thick slices and the possible slice misregistration between separate breath-holds.

Figure 7 Three slabs (each 64 mm thick with 32 partitions) were acquired using a 3D technique. First a multiplanar reconstruction (MPR) (b) was obtained along the line illustrated in (a). The origin of the right coronary artery at the aortic root was clearly identified in (b). A second MPR (d) was obtained along the line illustrated in (c). A segment of the right coronary artery is visualized in (d)

3D TOF imaging^{102–106} has also been used, but the motion induced blurring and ghosting severely degrade the image quality.

Background suppression increases the blood–tissue contrast and helps to delineate vascular details better. It also reduces vessel boundary blurring and ghosting artifacts from the physiological motion of the background tissue. Magnetization

transfer saturation can be used to suppress background with little effect on blood signal. While MTS is quite effective in enhancing vascular contrast in evaluating intracranial arteries, it suffers from high power deposition when used in body imaging. A selective inversion recovery, rapid gradient echo sequence¹⁰⁷ was proposed to suppress the background and background induced motion artifacts. Data acquisition takes

Figure 8 An MIP image of the pulmonary vasculature generated from an ECG-triggered 3D scan with 32 partitions, each 2 mm thick

place during diastole so that blood intravoxel dephasing due to pulsatile flow is minimized. An MIP image generated from this sequence is shown in Figure 9.

The contrast agent gadolinium diethylenetriaminepentaacetic acid (Gd-DTPA) has been successfully used in enhancing the vascular contrast in imaging the abdominal arteries. A continuous injection instead of a bolus was utilized to enhance arteries but not veins.¹⁰⁸ Two studies measured the renal blood flow using cine phase contrast methods.^{109,110} The flow measurements correlate closely with renal clearance of *p*-aminohippurate. The same sequence was also used to measure the volumetric flow rates in the portal venous system.¹¹¹ Technical improvement and better hardware are needed to improve the spatial resolution further.

5.5 Peripheral Imaging

Imaging of slow flow is difficult because of the saturation of blood. The use of an intravascular contrast agent makes it

Figure 9 An MIP image of renal arteries from a 3D diastolic acquisition and selective inversion recovery background suppression. The original data set has 32 partitions, each 1.25 mm thick

Figure 10 An example set of 3D limited volume-of-interest maximum intensity projection images in the leg post contrast agent injection. (a) Image collected during the arterial phase over 30 s with 50 slices and a resolution of $1\text{ mm} \times 1\text{ mm} \times 2\text{ mm}$. (b) Image collected afterward for a period of roughly 10 min with 100 slices and a resolution of $1\text{ mm} \times 1\text{ mm} \times 1\text{ mm}$. (c) Image is a processed version of the central image using the phase difference between veins and arteries to suppress the venous signal

possible to collect rapid, 3D, projective, coronal images of both legs in roughly 30 s. With 25 mT m^{-1} gradients and a rise time of $300\text{ }\mu\text{s}$, an in-plane resolution of 1 mm by 1 mm and a through plane resolution of 2 mm with 32 slices is possible in roughly 30 s with a TR of 5 ms.^{112,113} Higher resolution covering the entire leg is possible for scans of several minutes but then arteries and veins become equally bright. Figure 10a shows a rapid early first-pass scan of the vessels in which only arteries are enhanced, followed by a steady-state scan (Figure 10b) showing the enhanced veins as well (because the contrast agent has reached the same equilibrium value in both arteries and veins).

Three methods have been proposed to deal with this problem. The first is vessel tracking (mentioned above) and the second and third are developing methods using the T_2 and phase differences between arteries and veins. The shorter T_2 of venous blood can be used to suppress signals from veins while keeping those from arteries bright. This was accomplished in the 1980s using long echoes.¹¹⁴ In the late 1990s, using a T_2 preparation pulse and a spiral acquisition, reasonably fast high-resolution data can be collected¹¹⁵ where arteries are significantly brighter than veins and surrounding muscle. Alternatively, the phase can be used to suppress venous signal.¹¹⁶ This is possible because the venous blood has a different susceptibility from the surrounding tissue for vessels parallel to the static field (this difference is caused by the deoxyhemoglobin in the veins). Figure 10c shows the suppression of venous blood using this method (see below).

5.6 Venographic Imaging in the Brain

Angiography is a general term for imaging vessels, including both arteries and veins. Arteries are usually the focus of MRA studies, since they carry the crucial morphologic information as to the supply of blood to the tissue. However, if one

Figure 11 A minimum intensity projection image from a $TE=40$ ms, $TR=57$ ms, 3D, gradient echo image projected over seven images. The resolution is $0.5\text{ mm} \times 0.5\text{ mm} \times 2.0\text{ mm}$. The acquisition time was 10 min and 32 partitions (slices) were collected in total. The peripheral

is interested in whether or not the tissue actually performed its function and used the oxygen delivered to it, then the venous image is important. The use of intravascular contrast agents makes it possible to visualize both arteries and veins. How to separate them remains the problem. However, one method exists that can highlight small venous structures even without a contrast agent. This method uses a high resolution, long TE , 3D gradient echo approach to reduce susceptibility effects caused by static field inhomogeneities, and to highlight the field differences between arteries and veins^{117,118} caused by the differences in deoxyhemoglobin content. The field difference between veins and arteries is about 0.3 p.p.m. for veins parallel to the static field and leads to an out-of-phase relationship between them that occurs for a TE of roughly 50 ms. This π phase shift leads to a cancellation effect between the background tissue and the veins. Further, the phase image itself reveals the same π phase shift and can be used to suppress the venous signal simply by scaling the phase image to unity where the phase is zero and to zero when the phase is π ; the resulting phase mask is then multiplied by the magnitude image. Figure 11 demonstrates the level of cancellation and the visualization of small venous structures in the brain. This approach has proven valuable for the study of venous lesions and other vascular abnormalities.

6 FUTURE DIRECTIONS

Future developments depend on what remains unanswered using the present techniques and what new directions remain to be investigated. In the former category, the use of short (possibly velocity compensated) gradient echoes, enhanced contrast

for TOF imaging, faster imaging, and phase unwrapped images for an improved S/N for phase contrast quantitative flow imaging are major areas for continued research. In the latter category, major new directions include the use of intravascular or higher relaxivity contrast agents, echo planar flow imaging, fluid dynamic applications, the use of phase coil arrays, the acquisition of larger matrix sizes (1024 or even 2048) and better postprocessing and display techniques. As far as whether TOF or phase contrast is better, this may become a moot point as both methods become less competitive and more complementary due to the increased speed of acquisition possible with new systems today. With both high resolution images and functional information, MRA promises to be the ideal way to obtain most vascular information noninvasively.

Blood Flow: Quantitative Measurement by MRI

David N. Firmin

National Heart and Lung Institute, University of London, UK

and

Raad H. Mohiaddin

Royal Brompton Hospital, London, UK

1 INTRODUCTION

The study of flow with nuclear magnetic resonance (NMR) has a long history, although the early research work merely set out to analyze the flow effects on the signal without detailing a particular application. Hahn,¹ for example, was the first to note the effect of diffusion while the first to study the effect of coherent flow was Suryan.² Several years later methods of flow measurement were presented, a number of which were designed for the measurement of blood flow. The methods all used either flow-related phase shifts or time-of-flight principles, where the latter could involve tagging or saturation and wash-in effects. Following the introduction of NMR imaging techniques, a number of methods were described, again applying the same principles, but for obtaining flow information in the form of an image.

2 EARLY QUALITATIVE IN VIVO STUDIES

Much of the initial work concentrated on understanding the appearance of a flow on an image and the artifacts it can cause; these can often be indicative of the type of flow present and can therefore give important information in the diagnosis of a particular disorder. Examples of flow phenomena studied include: signal dephasing,³ wash-in/wash-out with different sequences,⁴⁻⁶ even echo rephasing,⁷ and signal mis-registration effects.⁸ Pulsatile flow can also alter the appearance of the image by the formation of nonstructured flow artifacts. These result because the motion of blood during the application of imaging gradients results in a phase shift of the blood signal which is added to the spatial phase encoding. If the motion of blood changes from one acquisition to another, the resultant phase shift will introduce a varying error to the spatial phase encoding. The Fourier transform will then get 'confused' and the blood signal will end up being spread out along the phase encoding axis. Perman et al.⁹ investigated this type of flow artifact and demonstrated that even echo rephasing corrected the error and removed the artifact as long as the motion was reasonably simple (i.e. it did not contain significant acceleration or other high-order derivatives of position).

3 EARLY QUANTITATIVE IN VIVO STUDIES

The quest for a method quantitatively to image blood flow in vivo was first realized in the early 1980s, initially using time-of-flight methods and soon afterwards phase methods.

3.1 Time-of-Flight Methods

Singer and Crooks⁶ initially used a saturation wash-in technique in an attempt to measure flow in the internal jugular veins. They employed the same principles as first Garraway¹⁰ and then Thulborn et al.¹¹ had previously used in vitro. The method involved first saturating the slice and then leaving an interval before acquiring image data from the slice; the longer the time interval τ the greater the inflow of fully magnetized spins and the higher the signal on the image. The two main problems with these methods were that only low flow velocities could realistically be measured with practical slice thicknesses, and also many other factors could affect the amplitude of the blood signal.

Later work on this type of method tended to be more related to angiography, although some quantitative flow measurements were demonstrated.^{12,13} However, the advent of 3D imaging techniques has enabled ungated measurements of constant flows or averaged pulsatile flows to be carried out by using the time-of-flight principles as described below.

The first true time-of-flight (TOF) method of blood flow imaging was described by Feinberg et al.¹⁴ Their approach was to use a variation on a double echo spin echo sequence; the first 180° selected slice was displaced by 3 mm from the 90° selected slice, and the second was displaced by 9 mm. The first 180° selection overlapped sufficiently with the 90° selection to produce a good anatomical image. The second 180° pulse selection did not overlap with that of the 90° or the first 180° pulse selection, and hence produced no anatomical image but gave a high signal from the blood that had experienced all the preceding rf pulses (i.e. that had passed between the different selected planes). Flow in the carotid and vertebral arteries of a volunteer's neck was identified with the technique.

One-dimensional methods that directly imaged blood movement over a known time were described by both Shimizu et al.¹⁵ and Axel et al.¹⁶ The methods consisted of slice selection and frequency encoding being applied in the same axis. In this way material that had moved in this axis between selection and reading would be displaced relative to the stationary material. This technique is therefore making use of an effect that is often seen as a problem in other methods of flow imaging. With the flow information encoded in one axis as described, the other one or two axes may be spatially encoded by use of phase-encoding gradients. Shimizu et al.¹⁵ tested the technique on a U-tube phantom where, by varying the velocity and the echo time (TE) to produce different flow displacements, they found very good correlation between these displacements and true flow. The technique was demonstrated in vivo¹⁷ where it was repeated rapidly throughout the heart cycle so that pulsatile flow information could be acquired in a reasonable time. One of the main advantages of the technique was its ability to image very high velocities.

Figure 1 Inflow of arterial blood (up) and venous blood (down) into a presaturation band in a 2D cardiac gated image. The saturation has taken place just above the carotid bifurcation during systole. The time between the saturation pulse and the echo time is 18 ms. The distance the blood has moved is slightly more than 1.2 cm, resulting in a velocity of about 60 cm s^{-1} . (Reproduced with permission of Aspen Publishers from E. M. Haacke, A. S. Smith, W. Lin, J. S. Lewin, D. A. Finelli, and J. L. Duerk, *Top. Magn. Reson. Imaging*, 1991, 3, 34)

Methods have also been developed combining the time-of-flight and wash-in/wash-out principles. Two general approaches using slice saturation in an orthogonal plane to that of the image have been used. The first utilizes the pulse to saturate tissues within a band across the image so that magnetized blood flowing into the region can be imaged and flow quantified by measuring the distance of inflow over the time between saturation and image acquisition. Results have been demonstrated using two-dimensional cardiac gated (Figure 1) and three-dimensional ungated methods (Figure 2). The second approach is to saturate a band of tissue, for example in a transverse plane, and then follow the progress of this dark band in the coronal or sagittal planes.¹⁸

The main limitation of these saturation techniques is that they are limited by the T_1 value of the tissue. The signal from the saturated blood or tissue will increase towards equilibrium with time, eventually making it difficult to measure accurately the distances traveled. Also, motion during the sampling gradients can result in signal distortion and thus affect the image.¹⁹ For arterial flow measurements where cardiac gating is required, only two-dimensional images can realistically be acquired. This limits our ability to study flow details as the flow profile can only be acquired in one dimension at the most.

3.2 Phase Methods

In 1982, Moran²⁰ suggested the introduction of bipolar velocity phase-encoding pulses, such as had previously been used

Figure 2 Inflow during a 3D TOF experiment carried out in the upper neck/head region reveals many arterial vessels. The peak flow represented in the internal carotid is more than 1 m s^{-1} . (Reproduced with permission of Mosby-Year Book, Inc. from D. N. Firmin, C. L. Dumoulin, and R. H. Mohiaddin, in 'Magnetic Resonance Angiography, Concepts and Applications', ed. E. J. Potchen, E. M. Haacke, J. E. Siebert, and A. Gottschalk, 1993)

in nonimaging experiments, in order to introduce velocity phase-encoding to the data. Phase methods of flow imaging that were later developed using this suggested theory fell broadly into two categories:

1. Fourier flow imaging methods that phase-encoded flow velocity so that a number of flow phase-encoding steps would separate the different flow velocities present in a particular region.
2. Phase-mapping methods that mapped the phase of the signal directly in order to measure the flow.

Both categories of methods are based on the same theory that the NMR signal from a sample of spins moving in the direction of a bipolar magnetic gradient pulse pair (Figure 3) will accumulate a phase shift given by:

$$\phi = \gamma v \Delta A_g \quad (1)$$

where γ is the gyromagnetic ratio, v is the velocity, Δ is the time between the centers of the lobes of the gradient pulse, and

Figure 3 A bipolar magnetic gradient profile as used to produce velocity-dependent phase shifts

A_g is the area of one gradient lobe. The phase shift is therefore directly related to the velocity for a particular gradient wave form.

3.2.1 Fourier Flow Methods

The first to demonstrate experimentally the method of Fourier flow imaging were Redpath et al.²¹ when they used eight flow phase-encoding steps to image a circle of fluid-filled tubing that was rotated in the image plane. Different segments of the circle were seen on the eight resultant images, each corresponding to a different velocity range in the direction of the flow phase-encoding gradient. Feinberg et al.²² applied the method both in vitro and in vivo, but increased the velocity resolution and simplified the reconstruction by increasing the number of flow phase-encoding steps and removing the spatial phase encoding. The phantom results proved the accuracy of the method and the in vivo study, while showing the flow in the descending aorta, also highlighted the problem of a very high signal from stationary tissue imaged in the spatial dimension. In 1988, Hennig et al.²³ described a development of this method where the signal from stationary tissue was saturated and the sequence repeated much more rapidly. The main problem with the technique, particularly when pulsatile flow is being studied, is that the time required to obtain a reasonably high resolution in the velocity axis precludes the use of more than one spatial dimension.

3.2.2 Phase Mapping Methods

In 1984, both van Dijk²⁴ and Bryant et al.²⁵ demonstrated the use of velocity phase mapping to measure flow velocity directly from the phase of the signal originating from each imaging voxel. These phase-mapping methods were made clinically more useful, partly by the use of a field echo sequence^{26,27} and, most importantly, by the introduction of velocity compensated gradient waveforms.^{28,29} The improvements enabled the sequence to be repeated rapidly and prevented the characteristic signal loss due to shear flow when uncompensated gradient waveforms were employed. The technique has been validated in vivo³⁰ and has already provided useful information in clinical and physiological flow studies.³¹

The accuracy of the techniques depends on numerous factors,³² although validation of the phase velocity mapping method has been demonstrated both in vitro and in vivo. In vitro measurements have been made by imaging a disk of doped water (1 mM CuSO_4) rotating at known rate and by comparing measurements of the flow of doped water through tubes with true flows. The in vivo validation³⁰ showed a very good correlation between the measurement of the stroke volume of the heart carried out by the phase mapping technique and a previously validated multislice volume method.

3.2.3 Rapid Flow Imaging Methods

The previously described methods acquire data over a long period of time in comparison to the cardiac cycle, and rapid variations in flow cannot be followed. In order to study flow dynamics, very rapid flow imaging techniques have been developed, either by imaging only one spatial dimension or by

combining a phase mapping type approach with a very fast imaging method such as echo planar.³³

The more obvious approach in many respects is to remove the slow spatial phase-encoding process and to image in only one spatial dimension. One such method, RACE (Real time ACquisition and velocity Evaluation),³³ was developed to measure flow perpendicular to the slice. The technique can be repeated rapidly throughout the cardiac cycle in order to give near real time flow information. Figure 4 shows examples of flow images acquired using the RACE technique. One problem with this type of approach is that data are acquired from a projection through the patient; this means that any signal overlapping with the flow signal will combine and introduce errors to the flow measurement. Several strategies have been suggested for localizing the signal in order to avoid this: they include spatial presaturation, projection dephasing (applying a gradient to suppress stationary tissue), collecting a cylinder of data, and multiple oblique measurements.

For 2D spatial resolution with velocity information, a very rapid technique such as echo planar is required. The echo planar method is technically difficult and not possible on many current standard machines. However, methods have been developed to minimize the technical difficulties and Figure 5 shows echo planar velocity images of a normal neck acquired in 40 ms of two consecutive cardiac cycles using such a method. Figure 6 shows a comparison of echo planar velocity measurements with those obtained using field even echo rephasing (FEER)²⁸ velocity mapping. The two techniques agree well although it should be remembered that one is an average over time and the other is not. An additional problem is that the conventional echo planar sequence has a relatively high phase sensitivity to flow in the phase-encode (blip) direction, even if additional flow compensation is applied. This has been used to advantage for more qualitative flow imaging, showing flow disturbances for example. Recent studies have concentrated on reducing the phase sensitivity and increasing the image matrices; one such approach is to use spiral echo planar where the phase sensitivity is reduced because the sampling starts at the center of k -space.³⁴⁻³⁶ An alternative is to combine phase mapping with subsecond FLASH techniques; here the limitation is the duration of the acquisition (>100 ms) and the relatively low spatial resolution.

Less rapid and higher resolution acquisitions can be made on standard MR imaging equipment by acquiring k -space in an interleaved fashion. FLASH, echo planar, or spiral imaging may be acquired in such a so-called segmented k -space approach. Cardiac gated images can be acquired over a period of approximately 16 cardiac cycles so that, although dynamic changes in flow cannot be monitored with this approach, images can be acquired in a breath-hold. The problems of respiration that have precluded imaging details such as the coronary arteries can thus be reduced or removed, and more reliable coronary flow measurements made feasible.³⁷

4 CLINICAL OBSERVATIONS AND APPLICATIONS

As described in the previous sections, magnetic resonance imaging (MRI) offers several methods for measuring blood

Figure 4 RACE profile through (a) five cardiac cycles in the neck and (b) four cardiac cycles in the abdomen. The carotid velocity is similar to that seen with Doppler ultrasound, never quite dropping to zero. The aortic flow is rapid and drops to zero and then returns to a fairly constant low flow rate. (Reproduced with permission of Aspen Publishers from E. M. Haacke, A. S. Smith, W. Lin, J. S. Lewin, D. A. Finelli, and J. L. Duerk, *Top. Magn. Reson. Imaging*, 1991, 3, 34)

flow which have greatly enhanced the potential capability of MRI as a physiological tool in cardiology. As yet the majority of clinical use has been with the method of phase shift velocity mapping, and for this reason alone many of the following observations and applications will concentrate on this approach.

4.1 Thoracic Aorta

Quantitative analysis of aortic flow using MRI has been a subject of considerable interest in health and disease. Normal systolic flow in the ascending aorta is plug flow with a skewed velocity profile which has higher velocities around

Figure 5 (a) A magnitude reconstruction of echo planar data acquired with one excitation. The selected region includes the carotid arteries (short arrows) and jugular veins (long arrows) which can be seen exhibiting high blood signal. (b) An example of a velocity phase map reconstructed from data acquired with one excitation of each of a modified and unmodified EPI flow sequence. Flow in the carotid arteries can be seen tending toward white whilst that in the jugular veins tends toward black with stationary material mid-gray. (Reproduced with permission of Academic Press from D. N. Firmin, G. L. Naylor, P. J. Kilner, and D. B. Longmore, *Magn. Reson. Med.*, 1990, 14, 230)

Figure 6 A comparison of the flow versus time plots for the right carotid artery of a normal volunteer obtained from echo planar velocity images and FEER velocity images. The close comparison between the two plots suggests that echo planar velocity measurements are as accurate as the FEER measurements. It should be noted, however, that the two types of flow information are somewhat different. (Reproduced with permission of Academic Press from D. N. Firmin, G. L. Nayler, P. J. Kilner, and D. B. Longmore, *Magn. Reson. Med.*, 1990, **14**, 230)

the inside of the arch. Throughout diastole the blood continues to move with simultaneous forward and reverse channels as is demonstrated in Figure 7.³⁸ In patients with coronary artery disease, the reverse flow channel is smaller and may enter any of the coronary sinuses.³⁹ In aortic valve regurgitation, the magnitude of the reverse flow is understandably increased (Figure 8 and Figure 9) and aortic or pulmonary regurgitation may be quantified from the backflow of blood in the proximal great vessels assessed by velocity mapping.⁴⁰

4.1.1 Aortic Flow Wave Velocity

Aortic flow wave velocity can be calculated by MR velocity mapping from the delay between the leading edge or onset of the flow wave in the ascending and descending limbs of the thoracic aorta.^{41,42} This parameter is closely related to aortic compliance⁴¹ which may prove to be useful for the detection and monitoring of arterial disease.

4.1.2 Aortic Dissection

Aortic dissection is readily detected by spin echo imaging and its extent can be displayed, including the involvement of other vessels.⁴³ However, a thin intimal flap may not be shown in these images unless static blood in the false lumen provides natural contrast with the true lumen. If there is any doubt, then the flap will be more easily seen using a gradient echo sequence, and velocity mapping will confirm the diagnosis by demonstrating the differential flow velocities in each lumen (Figure 10).⁴⁴

Figure 7 (a) A mid-systolic gradient echo image in a transverse plane through the great vessels of a healthy volunteer with (b) the corresponding velocity map. (c) The instantaneous flow volume curves of the ascending aorta (AA), main pulmonary artery (MPA), descending aorta (DA), and superior vena cava (SVC) calculated from the complete cine velocity map acquired in the same plane: 1, ascending aorta; 2, main pulmonary artery; 3, left atrium; 4, descending aorta; 5, superior vena cava. (Reproduced with permission of the American Heart Association from R. H. Mohiaddin and D. B. Longmore, *Circulation*, 1993, **88**, 264)

Figure 8 (a) Gradient echo images in a coronal plane acquired during ventricular diastole in a patient with Marfan's syndrome and aortic valve regurgitation. (b) Flow volume curves in the ascending aorta (AA) and descending thoracic aorta (DA) measured from the complete cine acquisition acquired in a transverse plane perpendicular to the AA and DA. Note the large retrograde net flow during diastole. (Reproduced with permission of the American Heart Association from R. H. Mohiaddin and D. B. Longmore, *Circulation*, 1993, **88**, 264)

4.2 Central Pulmonary Arteries

The retrosternal position of the central pulmonary arteries makes it difficult to assess pulmonary blood flow by Doppler echocardiography, especially in the presence of skeletal or lung abnormalities. Pulmonary flow profiles have been studied less well in patients but MR velocity mapping has confirmed an abnormally early forward systolic peak and increased reverse diastolic flow in patients with pulmonary hypertension.^{45,46}

Figure 9 Fourier velocity measurements using a thin-slice excitation in the abdomen of (a) a healthy volunteer and (b) a volunteer with a bicuspid aortic valve regurgitation. (Reprinted with permission of Mosby Publishers from D. N. Firmin, C. L. Dumoulin, and R. H. Mohiaddin, in 'Magnetic Resonance Angiography, Concepts and Applications', ed. E. J. Potchen, E. M. Haacke, J. E. Siebert, and A. Gottschalk, 1993)

This abnormal pattern (Figure 11) may be caused by reflected waves from the distal vasculature which has a high impedance. Patients with a single lung transplant are unique in that the cardiac output is ejected into two pulmonary vascular beds with different characteristics, and in these patients the differential blood flow depends on the relative resistance in each lung. Velocity mapping can assess the total and differential pulmonary blood flow which may be useful for monitoring these patients (Figure 12).⁴⁷

4.3 Caval Veins

The caval veins are relatively large, and reliable velocity maps and flow measurements can readily be obtained.⁴⁸ The normal pattern of caval flow has two forward peaks in ventricular systole and diastole (Figure 7), but this pattern is disturbed by disease. Any condition that causes impaired filling of the right ventricle reduces the diastolic peak, a pattern seen in constrictive and restrictive cardiac disease (Figure 13).⁴⁸ Tricuspid regurgitation attenuates the systolic peak of caval flow, sometimes to the extent that reverse flow occurs (Figure 14).⁴⁸ MR is commonly requested for the assessment of pericardial disease and therefore the ability to measure caval flow is an important adjunct, providing an estimate of the functional significance of the disease. In patients with obstruction of the superior vena cava, absence of flow can be confirmed and reverse flow in the azygous vein can be measured (Figure 15).⁴⁸

4.4 Pulmonary Veins

Normal pulmonary venous flow measured by MR velocity mapping shows two peaks of forward flow, one during ventricular systole and the other in diastole.^{49,50} A small back flow also occurs during atrial systole. A non-

Figure 10 (a) A spin echo image in an oblique plane through the ascending aorta, aortic arch, and descending thoracic aorta showing a dilated atherosclerotic thoracic aorta with an intimal flap (arrows) separating the true lumen [t] from the thrombosed false lumen [f]. (b) The systolic velocity image shows high velocity in the true lumen and zero velocity in the false lumen: 1, Left ventricle; 2, ascending aorta; 3, right pulmonary artery; 4, left atrium. (Reproduced with permission of the American Heart Association from R. H. Mohiaddin and D. B. Longmore, *Circulation*, 1993, **88**, 264)

compliant left ventricle produces high left atrial pressure during atrial systole, causing the retrograde flow in the pulmonary veins to become larger than the flow through the mitral valve. An attenuated systolic forward flow peak has been demonstrated in patients with mitral valve regurgitation and the degree of this attenuation correlates well with the severity of regurgitation.⁵¹

4.5 Portal Vein

The nature of the Fourier flow imaging technique, in that it only resolves one spatial dimension, requires that some form of signal localization is applied. Figure 16 demonstrates a method

of using a 2D selective rf pulse to excite a cylinder of tissue. Spatial resolution can then be obtained along the axis of the cylinder by use of the frequency-encoding gradient. The image, acquired in 9 s, displays flow in the portal vein and inferior vena cava.

4.6 Valvular Stenosis

A stenotic valve may be assessed by measuring the flow velocity in the jet of blood passing through the stenosis. In the case of a given flow, an increasingly narrow stenosis leads to an increase in the velocity of flow through the orifice. The relationship between the velocity of the jet and the difference between the pressures on either side of the stenosis can be approximated by the modified Bernoulli equation which in its simplest form is:

$$\Delta P = 4V^2 \quad (2)$$

where ΔP is the pressure drop across the stenosis in mmHg and V is the velocity in m s^{-1} .

Accurate velocity mapping of stenotic jets by MRI requires the use of very short echo times.^{49,52,53} The velocity map may be through-plane with the jet passing perpendicularly through the chosen imaging plane, or in-plane when the imaging plane is chosen to encompass the length of the jet (Figure 17). In-plane imaging yields a greater number of pixels for the analysis of velocity, but if the jet is small in-plane imaging is less reliable because of partial volume effects and movement of the jet out of the imaging plane. It is preferable to acquire data in both planes.

4.7 Flow in the Coronary Arteries

The development of fast imaging techniques has improved the ability of MRI to image directly the proximal portions of both the left and right coronary arteries, but these are not comparable in quality with X-ray angiograms.^{54,55} It is doubtful however that the place for MR is simply as another method of demonstrating coronary anatomy, subject to interpretation but revealing no information about flow in the vessels. The feasibility of MRI for the measurement of flow in the epicardial coronary arteries has been demonstrated (Figure 18).^{37,56} Coronary artery bypass grafts can be assessed using MR velocity mapping.⁵⁷ However, flow measurement within the grafts is not always possible because of signal loss due to sternal suture and clips left after surgery.

4.8 Peripheral Arteries

Peripheral atherosclerosis produces clinical problems either by reducing blood flow or by the release of emboli from ulcerated plaques. Arterial stenosis can be detected and its severity can be assessed from measurement of changes in the velocity profile across the stenosis using MR velocity mapping (Figure 19). The flow ratio in paired vessels, like the iliac arteries, is greater than 0.85 in healthy volunteers (Figure 20) and less

Figure 11 Main pulmonary artery flow volume curves measured by cine resonance velocity mapping (a) in a normal subject and (b) in a patient with pulmonary arterial hypertension: ■ = net flow; + = forward flow, ♦ = reverse flow. In the patient studied, the net flow, forward, and reverse flow were irregular and the reverse flow was relatively large. (Reproduced with permission of Mosby-Year Book, Inc. from H. G. Bogren, R. H. Klipstein, R. H. Mohiaddin, D. N. Firmin, S. R. Underwood, R. S. O. Rees, and D. B. Longmore, *Am. Heart J.*, 1989, **118**, 990)

Figure 12 (a) A spin echo image of the pulmonary artery bifurcation of a patient with left lung transplantation. (b) Flow curves of the main (MPA), right (RPA), and left (LPA) pulmonary arteries of the same patient calculated from the complete cine velocity mapping. Blood flow in the transplanted left pulmonary artery is qualitatively and quantitatively different from that in the native right pulmonary artery. (c) Flow-volume curves of the MPA, RPA, and LPA pulmonary arteries calculated from the complete cine velocity mapping acquired in a healthy volunteer. Flow in the RPA and LPA is qualitatively and quantitatively similar: 1, main pulmonary artery; 2, right pulmonary artery; 3, left pulmonary artery; 4, ascending aorta; 5, descending aorta. (Reproduced with permission of the American Heart Association from R. H. Mohiaddin and D. B. Longmore, *Circulation*, 1993, **88**, 264)

Figure 13 (a) A spin echo image in a transverse plane at mid-ventricular level in a patient with constrictive pericarditis showing pericardial thickening (arrows). (b) Superior vena caval flow curve of the previous patient measured from the complete cine velocity map acquisition throughout the cardiac cycle. The diastolic peak is attenuated which implies impaired right ventricular filling: 1, left ventricle; 2, right ventricle; 3, right atrium. (Reproduced with permission of the American Heart Association from R. H. Mohiaddin and D. B. Longmore, *Circulation*, 1993, **88**, 264)

Figure 14 Superior and inferior vena caval flow curves in a patient with tricuspid valve regurgitation. The systolic peak is attenuated and there is retrograde flow in the inferior vena cava in systole. (Reproduced with permission of RSNA Publications from R. H. Mohiaddin, S. L. Wann, S. R. Underwood, D. N. Firmin, R. S. O. Rees, and D. B. Longmore, *Radiology*, 1990, **177**, 537)

Figure 15 Flow curves in the superior and inferior venae cavae in a patient with a rhabdomyosarcoma and obstruction of the superior vena cava showing high flow with a normal pattern in the inferior vena cava, absent flow in the superior vena cava, and retrograde flow in the azygos vein. (Reproduced with permission of RSNA Publications from R. H. Mohiaddin, S. L. Wann, S. R. Underwood, D. N. Firmin, R. S. O. Rees, and D. B. Longmore, *Radiology*, 1990, **177**, 537)

Figure 16 Images from a velocity quantification protocol. (a) Geometry of the procedure. The patient is placed in a supine position. The axis of the cylindric excitation is in the patient's anteroposterior (AP) direction. The direction of the flow-encoding gradient is oblique to the major axes and is chosen to be aligned with the portal vein. The frequency-encoding axis is chosen to be coincident with the axis of the cylindric excitation pulse. (b) Coronal pilot image (acquisition time 20s for five images). (c) Quantitative velocity image in which the horizontal axis is in velocity units and the vertical axis represents spatial displacement of the measured flow along the AP dimension. (Reprinted with permission of Mosby Publishers from D. N. Firmin, C. L. Dumoulin, and R. H. Mohiaddin, in 'Magnetic Resonance Angiography, Concepts and Applications', ed. E. J. Potchen, E. M. Haacke, J. E. Siebert and A. Gottschalk, 1993)

Figure 17 (a) A gradient echo image and (b) a corresponding velocity map in a patient with aortic stenosis. The unusual oblique plane was necessary to orient the abnormal jet direction vertically for velocity encoding. Velocity profile displayed in the center of the jet recorded a peak velocity of 3.3 m s^{-1} (44 mmHg): 1, the left ventricle; 2, ascending aorta; 3, pulmonary artery; 4, right atrium. (Reproduced with permission of the American Heart Association from R. H. Mohiaddin and D. B. Longmore, *Circulation*, 1993, **88**, 264)

than 0.85 in patients with tight stenosis of one iliac artery [Figure 21(a)].⁵⁸ In patients studied pre- and postangioplasty, the preangioplasty ratio was 0.31 and postangioplasty improved to 0.79 [Figure 21(b)]. This finding was supported by improvement in the walking distance and in the peripheral Doppler pressure measurement (the posterior tibial/brachial artery index was right = 1, left = 0.88 on the preangioplasty recordings and right = 1, left = 0.96 on the postangioplasty recordings).⁵⁸

Figure 18 (a) In-plane early diastolic magnitude images and (b) velocity map of a normal left anterior descending coronary artery (LAD). The peak flow was measured at 12 cm s^{-1} . (LV, left ventricle; RV, right ventricle). (Reproduced with permission of Williams & Wilkins from J. Keegan, D. N. Firmin, P. D. Gatehouse, and D. B. Longmore, *Magn. Reson. Med.*, 1994, **31**, 526)

4.9 Congenital Heart Disease

MR velocity mapping has been very successful in grown-up patients with congenital heart disease.^{52,59,60,61} Intra and extra cardiac shunting can be measured in a number of ways by MR velocity mapping. Flow directly through atrial and ventricular defects can be visualized [Figures 22(a) and (b)], but the best method has been to measure the pulmonary (Q_p) to systemic (Q_s) ratio directly from aortic and pulmonary flow [Figure 22(c)].⁶⁰ Other structures of interest for the measurement of flow are surgically created shunts and conduits, and baffle obstruction following the Mustard procedure (see section 5, *). The technique is also useful for following up patients after Fontan's operation and its modifications (see section 5, †). The hemodynamic significance of aortic coarctation or recoarctation can be assessed noninvasively by MR velocity mapping.⁵⁹ The modified Bernoulli equation can be used to calculate the pressure difference across the diseased

Figure 19 Multiple atheromatous plaques causing stenoses of both common iliac arteries and the origin of the left internal and external iliac arteries (arrows). (a) Spin echo image. (b) Magnetic resonance velocity map in the same plane as (a) showing velocity profiles across [1] the abdominal aorta, [2] the right, and [3] the left iliac arteries. There is increased peak velocity in both iliac arteries compared with the aorta. The peak velocity is greater in the left iliac artery which demonstrates that the stenosis on the left is greater than that on the right. (Reproduced with permission from R. H. Mohiaddin, C. Sampson, D. N. Firmin, and D. B. Longmore, *Eur. J. Vasc. Surg.*, 1991, **5**, 383)

Figure 20 Flow curve in the abdominal aorta, and right and left iliac arteries of a volunteer. Flow is qualitatively similar in the three arteries and quantitatively similar in the R and L iliac arteries. (Reproduced with permission from R. H. Mohiaddin, C. Sampson, D. N. Firmin, and D. B. Longmore, *Eur. J. Vasc. Surg.*, 1991, **5**, 383)

segment from peak jet velocity in the coarctation. Abnormalities in aortic volume flow and aortic flow waveforms distal to the coarctation can also be measured and could represent an additional index for monitoring the hemodynamic significance of coarctation or recoarctation in patients (Figure 23).⁵⁹

5 NOTES

*Mustard's operation was designed to redirect the inflow streams of blood in patients with congenital disease of transposition of the great arteries. The atrial septum is removed and a saddle-shaped baffle (Dacron or pericardial) is placed within the atria to direct the systemic venous blood through the mitral valve to the left ventricle, and pulmonary artery and pulmonary venous blood to traverse the tricuspid valve to the right ventricle and aorta.

†Fontan's operation was designed to redirect systemic venous blood in patients with tricuspid atresia to the pulmonary arterial circulation. The right atrial appendage is usually connected to the pulmonary trunk. Modifications of Fontan's operation have been used for other complex cardiac malformations.

Figure 21 Flow in the abdominal aorta and R and L iliac arteries of a patient (a) before angioplasty and (b) after angioplasty. The flow in the left artery has improved and it is interesting to note that the flow in the right artery has decreased. (Reproduced with permission from R. H. Mohiaddin, C. Sampson, D. N. Firmin, and D. B. Longmore, *Eur. J. Vasc. Surg.*, 1991, **5**, 383)

Figure 22 (a) Gradient echo image showing a large atrial septal defect (arrow). (b) Velocity map of the same slice encoded from bottom to top of the image (posterior to anterior). The left-to-right shunt through the defect is seen black. (c) Flow volume curve of the main pulmonary artery (Q_p) and the ascending aorta (Q_s) in the same patient (Q_p/Q_s ratio = 1.9): 1, left atrium; 2, right atrium; 3, aorta; 4, main pulmonary artery. 1 INTRODUCTION

On the basis of the high soft tissue contrast of MRI and based on suspected differences of T_1 and T_2 values between benign and malignant breast tissues, MRI was initially considered to be a particularly promising tool for breast imaging. Unfortunately, the expected tissue characterization by MRI could not be demonstrated despite intense further research; signal intensities on various pulse sequences, and in vivo calculated T_1 and T_2 values, varied significantly in both benign and malignant tissues. Both MR parameters and signal intensities seemed to correlate well with the water/content, cells or fibrosis within the corresponding tissues, but did not allow a reliable distinction between benign and malignant tissues. This has proven true until today, even after the application of more sophisticated evaluation such as computer-aided evaluation methods.¹⁻⁵ For this reason, plain MRI (= MRI without contrast agent) does not play a role in the detection and diagnosis of breast malignancy nowadays. The disappointing results mentioned above, however, initiated work concerning the use of contrast agents for MR of the breast and the very encouraging results caused its further exploration.⁶⁻⁸ Today contrast-enhanced MRI of the breast is developing as an important additional tool for breast diagnostics, providing new information which is different from that of conventional imaging and is thus most valuable in certain problem areas of conventional breast diagnostics.⁹⁻²⁸

In one special area, however, both tomographic imaging and the high soft tissue contrast of plain MRI has proved helpful; this special area concerns the evaluation of the integrity of silicone implants.²⁹⁻³³ This chapter will provide an overview of these two major applications of breast MRI; plain MRI for the evaluation of implant integrity and contrast-enhanced (CE) MRI of the breast.

2 PLAIN MRI — DETECTION AND DIAGNOSIS OF IMPLANT FAILURE

Based on the latest knowledge concerning potential hazards caused by leaking or ruptured implants and free silicone, the detection of possible implant failure has become an important new demand. The capabilities of conventional methods such as mammography and ultrasound for detecting extra- and particularly intracapsular leakage are very limited. Hence the use of MRI in this field has been evaluated.

At present, various combinations of pulse sequences are still being tested. These use differences of T_1 , of T_2 , and of the resonance frequency of silicon compared with the surrounding fat, fibrosis, or glandular tissue.²⁹⁻³³ In general, a combination of at least three pulse sequences is recommended. These should, for example, include a T_1 -weighted pulse sequence with and without fat suppression, and one with silicone or water suppression as well as a fast high-resolution T_2 -weighted pulse sequence. The suppression of fat, water, or silicone can be obtained by spectrally selective pre-saturation pulses or by signal nulling with IR sequences. In order to cut potential ruptures orthogonally, these pulse sequences are usually applied in different planes (coronal, transverse, and/or sagittal). For the detection of discrete ruptures, at least one of the pulse sequences should allow slice thicknesses below 2–3 mm. For the other pulse sequences, a slice thickness below 5 mm appears optimal.

The implant itself is generally covered by a fine shell, which in intact implants can usually not be recognized since it is directly attached to the capsule of fibrous tissue which surrounds the implant. When the shell of the implant is ruptured, silicone can leak. Depending on whether the leakage of silicone is confined to the area surrounded by the fibrous capsule, or whether the leak is beyond the fibrous capsule (about 5% of the ruptures), the rupture is called intra- or extracapsular.

The following signs indicating a rupture have so far been described (Figure 1):

1. **Linguine sign:** The shell is ruptured, silicone remains predominantly within the fibrous capsule, and the collapsed shell floats within the silicone. The tomographic slices show wavy dark lines within the silicone, which represent the collapsed implant shell floating within the silicone. The wavy lines are called 'linguine'.

Figure 1 Morphological MR signs of implant rupture: (a) 'linguine sign'; (b) 'keyhole sign' or 'reverse c-sign' (right), and (c) 'droplet sign' in double lumen implant

2. When silicone enters between the shell and the fibrous capsule, silicone becomes visible outside the shell. Depending on the shape of the shell in this area, this sign is called 'c-sign' or 'keyhole sign'.
3. In double lumen implants, saline may enter the silicone lumen of the implant. Since saline and silicone gel do not mix, small droplets become visible; this sign is called the 'droplet sign' or the 'salad oil' sign.
4. Finally small droplets of silicone can be visualized outside the capsule. This sign indicates extracapsular rupture.

To date, with careful examination techniques using several pulse sequences and thin slices, very good sensitivities (above 80%) and specificities (above 90%) have been reported.^{29–33}

3 CONTRAST-ENHANCED MRI OF THE BREAST

Based on the unsatisfying results of plain MRI mentioned above, CE MRI of the female breast has been performed and investigated by us since 1985.^{6–8,16,17,21,22,28} Other workers have followed and contributed significantly.^{9–15,18–20,23–27} Today, contrast-enhanced MRI is gaining increasing importance as an additional tool for breast diagnostics.

3.1 Principles of Contrast-Enhanced MRI of the Breast

The complete breast is examined with thin and contiguous slices before and after the i.v. application of Gd-DTPA. By comparison of the corresponding pre- and postcontrast slices, tissue enhancement can be detected or excluded.

The fact that the large majority, possibly all, invasive breast malignancies do enhance is supported by the following fundamental data:^{34–40} (i) an increased number and size of vessels has also been encountered histologically in and around breast malignancies, as studies with special vascular staining show; (ii) according to in vivo animal experiments, vessel sprouting seems to be a prerequisite for tumor growth beyond a size of about 2–3 mm; (iii) tumor growth seems to depend on both increased vascularity and increased vascular permeability; (iv) both increased vascularity and vascular permeability are induced by so-called angiogenesis and permeability factors, numbers of which have already been identified; (v) cells from both invasive and numerous in situ carcinomas were able to induce vascular sprouting when transplanted on an animal cornea, while cells from normal breast tissue could not induce such changes; (vi) it has also been reported that cells from several benign entities were equally well able to produce identical or similar angiogenesis and permeability factors leading to similar vascular changes as in malignancy. Benign changes with similar capabilities included some proliferative dysplasias, healing wounds, and benign tumors.

The above-mentioned observations support many of the MR findings. They may also serve to explain both the reported excellent sensitivity and the limited specificity of CE MRI.

3.2 Techniques

For prognostic reasons, it is generally agreed that breast imaging techniques should be able to image carcinomas of 5
